An Address

ON

CLINICAL VARIETIES OF BRIGHT'S DISEASE.

Delivered before the Islington Medical Society

BY JOHN ROSE BRADFORD, M.D., D.Sc., F.R.C.P. LOND., F.R.S.,

PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL.

GENTLEMEN,—When accepting the invitation of your secretary to deliver an address before your society it occurred to me that it would be more agreeable to the members if I selected a clinical subject, and therefore I propose to address you on some views as to the clinical varieties of Bright's disease and some of the difficulties that are met with in practice in the differential diagnosis of this disease.

Bright's fundamental discovery was that albuminuria associated with dropsy was sometimes dependent on gross disease of the kidneys and he recognised that the malady presented many forms both clinically and in the post-mortem room, although he himself considered the relationship, if any, existing between the different varieties of kidney lesion an open question. At the present day some pathologists hold the view of what may be called the unity of Bright's disease, looking upon the diverse renal lesions found after death as due to different stages in the course of one and the same malady. Thus, for instance, it has been thought that Bright's disease, after existing for a variable period in an acute stage, might become chronic and that in the latter state it was associated with the lesion known as the "large white kidney"; and that subsequently to this other morbid processes might lead to the shrinking of the organ with an overgrowth of fibrous tissue, leading ultimately to the development of a contracted kidney. According to this view the large white kidney and some forms of contracted kidney would only be stages in the evolution of one and the same malady, much in the same way as it has been held that atrophic cirrhosis of the liver may be preceded by a condition of so-called "hypertrophic cirrhosis."

There are many difficulties, however, in the way of accepting this view, and other observers have considered that the different forms of renal lesion found at the time of death are really independent of one another and not stages in the evolution of one and the same morbid process. Thus, to take the case of the liver again, there are many facts which would fit in with the view that alcohol may in one patient produce so-called "hypertrophic cirrhosis" and in another atrophic cirrhosis, and that the latter is not merely to be looked upon as the sequel of the former. It is possible that that form of Bright's disease which has been so often described as the large white kidney is the complete expression of one morbid process, and that the contracted kidney is an independent affection produced by another morbid process. The relationship existing between the different forms of Bright's disease which are found in the post-mortem-room is one not only of interest to the pathologist, but is of great importance to the clinician, since the prognosis and the complications, and even the treatment, of the different varieties are by no means the same, and it is a matter of great importance to form an accurate diagnosis if possible of the particular renal lesion that is present in any given case.

The different forms of Bright's disease may be classified in a great variety of ways; thus frequently they are classified according to their etiology—Bright's disease following acute diseases, that following exposure to cold, that due to the action of certain poisons such as alcohol and mineral salts, that associated with pregnancy, and so forth. On the other hand the disease may be classified according to the lesions found, and thus many varieties—parenchymatous nephritis, glomerulo-nephritis, and mixed nephritis—have been recognised. Of recent years, however, it has been more and more shown that Bright's disease and nephritis are generally, if not always, due to the action of certain poisons on the renal structures and that these poisons tend to produce their effects more especially on the glomeralar tufts and on the renal epithelium. Although some differentiation may be made in that certain poisons, like cantharidin and turpentine, have an especial action on the glomerular epithelium, and others, like mineral poisons such as lead, produce their effects more especially on the epithelial structures, yet no hard-and-fast line can be drawn between the two. This is more especially so from the fact that if the glomerular circulation is profoundly interfered with the nutrition of the epithelial structures of the convoluted tubules must necessarily become impaired, and therefore it is probable that no morbid process will produce an exclusive action on any single element of the kidney. Further, all lesions, both of the glomeruli and of the epithelial structures of the tubules, are accompanied by a variable amount of change in the connective tissue of the organ, and thus it comes about that glomerulo-nephritis, parenchymatous nephritis, and interstitial nephritis are really, strictly speaking, theoretical lesions—unless we mean by "glomerulo-nephritis" merely a condition in which the lesions in the glomeruli are rather more marked than those elsewhere. An etiological classification is of no great value to the clinician and therefore a clinical classification is often of more immediate use. If we classify the varieties of Bright's disease clinically we may recognise three forms—namely, the acute, the chronic, and the latent, understanding by the last the condition in which, notwithstanding the existence of very serious renal disease, symptoms of ill-health are either absent or very trivial until the development of sudden complications which draw attention to the existence of the underlying disease.

In recognising three clinical varieties of Bright's disease nephritis must be separated and also granular kidney. The relations of nephritis and congestion of the kidney to Bright's disease are very close, both as regards the morbid anatomy and also as regards the etiology, inasmuch as in acute congestion the lesions are essentially similar in character to those which are developed during the initial stages of acute Bright's disease. There is not only a close resemblance in the morbid anatomy of acute congestion of the kidney and the first stages of Bright's disease, but there is also a great resemblance in etiology, inasmuch as acute congestion of the kidney may unquestionably be produced by some toxic agents which also give rise to Bright's disease, and this is more especially the case in scarlet fever and other acute specific febrile processes. The albuminuria that is seen during the height of scarlet fever, typhoid fever, and pneumonia, formerly called a "febrile albuminuria," is in all probability dependent on the excretion of toxic bodies by the kidneys, just as Bright's disease is.

Although there is a great resemblance in the etiology, and to a certain extent in the morbid anatomy, between acute nephritis and acute Bright's disease, yet there are considerable clinical differences. The absence of dropsy in acute nephritis and its frequent presence in Bright's disease is one of the most striking of these differences. Further, although the same morbid process in scarlet fever may give rise to acute nephritis and to acute Bright's disease, the former is developed at an early stage of the malady, whereas Bright's disease when produced by scarlet fever generally occurs later or even during convalescence. The mere occurrence of the secretion of a concentrated urine loaded with albumin and perhaps containing blood is by no means sufficient for the diagnosis of acute Bright's disease, since these effects may be produced not only by acute nephritis but also as a result of embolism or infarction of the kidney dependent on heart disease or other causes. Although the main clinical distinction between acute nephritis and acute Bright's disease is the presence of dropsy in the latter and its absence in the former, this is perhaps not an absolute distinction, as anomalous cases of acute and even of fatal so-called "Bright's disease" may occur without the development of dropsy. This shows how difficult it is to draw a hard-and-fast line between acute nephritis and acute Bright's disease, and some authorities look upon the two as synonymous, acute Bright's disease being nothing more than acute nephritis. We may put the matter in another way by saying that we may recognise two clinical varieties of acute Bright's disease—one where the patient not only passes a scanty, highly albuminous, blood-stained urine, but where in addition he suffers from typical renal dropsy, and a second variety where the only effects produced by the malady are urinary, the urine being loaded with blood, albumin, and casts, &c. Provided that we recognise these two definite varieties

it is a matter of no great moment whether we restrict the term of acute Bright's disease to the one and call the other acute congestion of the kidney, or if we call them both acute Bright's disease and look upon the one that is unaccompanied by dropsy as generally more favourable both immediately and remotely than the first. The fact remains that these two forms are seen clinically, but notwithstanding that they may have a similar etiology the ultimate outlook to the patient and the course of the malady are very different in the two cases.

The difficulties in separating acute Bright's disease from mere congestion of the kidney are considerable, but they are nothing compared with the difficulty which is found in recognising the different varieties of chronic Bright's disease and the relationship, if any, existing between chronic Bright's disease and acute Bright's disease. Chronic Bright's disease is a far more common malady, both in hospital and in private practice, than the acute, and every practitioner must be struck with the frequency with which he sees patients suffering from chronic Bright's disease in whom the most careful interrogation fails to reveal any history of acute Bright's disease accompanied by dropsy. At the present day the old view that chronic Bright's disease was generally the sequel of the acute disorder is no longer held with the tenacity that it formerly was and it is generally recognised that a great many cases of chronic Bright's disease, if not the majority, are chronic and insidious from the outset.

Clinically two varieties of chronic Bright's disease may certainly be recognised. One is a condition in which the patient suffers from dropsy and passes a scanty and highly albuminous urine loaded with casts. This variety of the disease is familiar to every practitioner, and such patients usually come under observation either on account of the dropsy or on account of the anæmia and cachexia that are produced by the disease. In many such cases the onset of dropsy is the first symptom that attracts attention, and the suddenness of this onset may be such as to merit the term of "subacute." Probably the great majority of cases of Bright's disease accompanied by dropsy are of this type and certainly in my experience it is unusual to get a history of sudden onset with more violent symptoms, such as pain in the back, blood in the urine, &c. Although in the majority of cases the onset of the disease is gradual, it is, of course, undoubted that in a certain number of cases this condition follows more or less rapidly on acute Bright's disease and in a few it may result as a sequel of acute Bright's disease.

The other variety of chronic Bright's disease which is also exceedingly common is one where the patient presents no signs of dropsy and where, notwithstanding the fact that the urine is highly albuminous, the quantity is not greatly diminished and in some cases is considerably increased. In this second variety of the disease the patient comes under observation either on account of progressive weakness and anæmia and all the symptoms dependent on these or else on account of symptoms dependent on the disturbance of the circulation produced by the high tension and cardio-vascular changes associated with the disease. In many cases of this second variety of chronic Bright's disease the patient may present symptoms of very great impairment of nutrition that has occurred as a result of the renal lesion. Such patients, for example, are often greatly emaciated and may actually seek advice on account of the loss of flesh. In some cases pigmentation of the skin simulating that seen in Addison's disease is present. This second variety of chronic Bright's disease is much more likely to be overlooked—unless a routine examination of the urine is made—than the first, where the presence of dropsy and very often of gastro-intestinal symptoms immediately draws attention to the desirability of examining the urine. But where a patient comes under observation on account of loss of flesh or weakness and perhaps some headache from the arterial changes that have occurred, unless the urine be examined or the fundus oculi be looked at a very serious and grave disease may be overlooked.

These two varieties of chronic Bright's disease not only present different symptoms clinically, but the lesions found after death are also notably different. To the form of the disease where clinically dropsy is a prominent symptom the name of the "large white kidney" is usually applied. To the other form, characterised clinically by the absence of dropsy and the presence of grave nutritional and arterial changes, the term of "contracted kidney" or "contracted white kidney" is perhaps most applicable. This last condition, however, must be carefully distinguished from the true granular kidney which is not entitled to be regarded as a variety of Bright's disease and is really a degenerative lesion associated with widespread arterial changes.

We may, then, recognise three fundamental varieties of Bright's disease, all of which are common—viz., acute Bright's disease, chronic Bright's disease associated with dropsy, and chronic Bright's disease unaccompanied by dropsy but where serious nutritional disturbance is present. The term "large white kidney" was more applicable to the first variety of chronic Bright's disease in former years, when waxy degeneration was a more common phenomenon in the post-mortem room than it is now. Although it is difficult to get rid of the term "large white kidney" as descriptive of this variety of Bright's disease, as a matter of fact the really large white kidney is rarely seen in the post-mortem room at the present day, and one of the specimens originally described by Bright as an instance of this condition was one where amyloid changes were very marked.

In most cases of this form of Bright's disease the kidneys are found either of a normal size or else slightly above it, the cortex is increased in thickness, the capsule is thin and non-adherent, and on stripping leaves a pale, smooth, waxy-looking, and marbled surface, the pyramidal portions of the kidney being deeply congested. In the second variety of chronic Bright's disease the kidneys are always shrunken, often to a considerable extent, the capsule is thickened and slightly adherent, and on stripping leaves a coarsely granular but mottled surface, and the cortex is greatly diminished in amount, often measuring not more than one-eighth or one-sixth of an inch in width. In these cases of contracted white kidney arterial changes in varying amount are usually present. In many cases the heart is greatly hypertrophied and the arteries have undergone similar changes to those seen in advanced cases of granular kidney. In others the arterial and cardiac lesions are less marked, and the degree of cardio-vascular degeneration cannot be correlated accurately with the extent of the renal lesion, since in some cases the kidneys may be greatly shrunken and the arterial changes slight, and in others where the lesion has not advanced to such a great extent in the kidney arterial changes are more marked. The arterial changes in this variety of chronic Bright's disease can not only be often recognised clinically by the character of the pulse, but also by the state of the vessels in the fundus oculi. The importance of examining the optic disc in cases of suspected chronic Bright's disease cannot be over-estimated. In many cases a rigidity and wire-like appearance of the arteries of the fundus can be detected prior to the onset of albuminuric retinitis, although this also is common in such cases.

The most interesting problem presented by the cases of chronic Bright's disease where the kidneys are contracted is the relationship, if any, existing between this malady and the acute and the other form of chronic Bright's disease. As mentioned before, it was formerly thought by some observers that this variety of kidney lesion was only a late stage of chronic Bright's disease or a late sequel of acute Bright's disease. It may be that in a certain proportion of cases this contracted white kidney is the remote sequel to an attack of acute Bright's disease or even of acute nephritis. It may be that in some instances the acute and initial illness has been of so trivial a character as to have been overlooked. But even when these facts are borne in mind it is remarkable how frequently this contracted white kidney is seen in patients who not only give no history of any former attack of Bright's disease but in patients who give no history of any condition where dropsy was present or even of the occurrence of any acute specific disease. I have myself published a series of such cases elsewhere, all occurring in women under 30 years of age and all fatal, so that the diagnosis was confirmed by post-mortem observations, and where all investigations failed to reveal that these patients had suffered from any acute illness prior to the onset of the fatal illness, which in many cases apparently only lasted a few weeks. It would therefore seem probable that this form of Bright's disease might occur primarily without the patient having suffered from either acute Bright's disease or from what was called the "large white kidney." Many cases of this form of Bright's disease that have fallen under my own observation might in many instances be described as latent, inasmuch as they presented no serious symptoms of ill health until the onset of uræmia. In fact, this is the only variety of Bright's disease which is entitled to be described by the term "latent."

Many other differences might be described in the clinical

course of the two forms of chronic Bright's disease which I have sketched above, but the only other one to which I should like to draw attention is the frequency with which uræmic symptoms of a severe type are often associated with what I have described above as the "contracted white kidney." Uræmia in one or other of its forms may be met with in any destructive disease of the kidney, but a very large proportion of cases of acute uræmia, and even of so-called "fulminating uræmia," occur associated with the contracted white kidney. Many observers, including Fagge, have drawn attention to the frequency with which uræmia complicates renal disease in young persons and young adults—and this form of chronic Bright's disease is most frequently seen in the young. This affords another difference, if any more are required, between it and the granular kidney, which, as is well known, is usually seen in persons beyond middle life. Not only does acute uræmia occur with great frequency in cases of contracted white kidney, but in a considerable proportion of cases the patient seeks advice solely on account of the uræmic symptoms. In some cases the first sign of illness is the occurrence of violent uræmic symptoms of a maniacal type, sometimes a succession of epileptiform seizures, and not infrequently attacks of violent dyspnœa, occasionally of an asthmatic type. In a large number of cases the patient seeks advice for what may be called premonitory uræmic symptoms, such, for instance, as severe headache, and in more than one case that has fallen under my observation the patient has sought treatment for what would appear at first sight to be a severe migrainous headache, but where examination of the urine and of the fundus showed the presence of grave renal disease and where, in the course of a few days or weeks, severe and fatal uræmia occurred.

The uræmia that occurs with the contracted white kidney is not only remarkable for the suddenness of its onset and the violence of its symptoms, but in my experience it is also remarkably fatal, and I know of no instance with recovery where acute uræmic symptoms have developed in such a case. Acute uræmia occurring, on the other hand, with acute Bright's disease is by no means necessarily fatal, but where it occurs in association with chronic destructive lesions of the kidney it is a very grave symptom. Giddiness and rashes of a papulous, erythematous, or even of a bullous type are also not uncommon premonitory symptoms in such cases of the onset of uræmia, and although in most instances rashes occur when the uræmic symptoms are well developed in some they have preceded the onset of uræmia, and I know of one case where a young man sought advice on account of the occurrence of a papulous eruption, asserting that he was in good health, but in the course of a few days severe and fatal uræmia developed. In the great majority of cases the diagnosis of this form of Bright's disease is easy from the fact that it occurs in young persons, usually under 30 years of age, that it is unaccompanied by dropsy, that there are obvious signs of cardio-vascular changes such as cardiac hypertrophy, high tension pulse, and changes in the vessels of the fundus oculi; the urine is also abundant, of low specific gravity, containing a quarter or a third of albumin. In very exceptional cases the recognition of this condition may be difficult from the fact that apparently the urine may be free temporarily from albumin, and I have notes of two cases where the urine on examination failed to show the presence of albumin and where the patient came under observation for severe uræmia which was fatal, and where the post-mortem examination showed the presence of advanced and extensive disease of the kidneys.

Although we cannot look upon the contracted white kidney as simply a stage in the evolution of Bright's disease it is probable that it has a similar etiology to that of acute and of the other variety of chronic Bright's disease. Thus in some cases this variety of kidney is seen in persons who have been exposed to the action of lead, and in others a history may be obtained of the occurrence of scarlet fever or other acute disease during early life, but it must be confessed that in the bulk of cases the etiology of this affection is more or less unknown and that in the individual instances that present themselves to us we fail to recognise the cause of the disease. In a few cases more than one member of the same family have been affected. In this respect the disease resembles the true granular kidney, where the observations of Dickinson and others have shown that a family influence can be traced. Alcohol, although it plays a large part in the production of the other form of chronic Bright's disease, would not seem to be a very potent factor in the etiology of the contracted white kidney. I must confess that in the cases which have fallen under my own observation I have been unable in the majority of them to determine the cause, and in a considerable proportion one has been able to exclude alcohol and the occurrence of former acute nephritis. It is a form of Bright's disease which it is especially important to recognise owing to the fact that it does not produce any very marked or obvious symptoms until it is far advanced, and also owing to the fact that it tends to be complicated in such a large number of cases by acute and fatal uræmia.

I would conclude, therefore, by summarising the views that I have put before you shortly as follows. 1. That we may recognise two forms of acute Bright's disease, one characterised not only by the well-known urinary changes but also by the presence of dropsy, the other where dropsy is absent and where the distinction between the acute Bright's disease and mere congestion of the kidney is by no means easy. 2. That there are at least two forms of chronic Bright's disease—one where the patient secretes a scanty, highly albuminous urine and becomes markedly dropsical, the course of the malady being chronic and death occurring usually either from the mere water-logging of the tissues, or from the development of inflammatory complications, or from chronic or subacute uræmia. The second form of Bright's disease where the symptoms often run a latent course for an unknown period and where the patient ultimately seeks advice on account of very vague symptoms of ill-health, such as wasting, loss of strength, circulatory disturbance, or even where he does not seek advice until the onset of acute and fatal uræmia. In this form of the disease dropsy is absent, the urine is abundant and pale, and it contains a considerable quantity of albumin. It would seem that not only may chronic Bright's disease be chronic from the outset, but also that the two varieties of chronic Bright's disease are not necessarily different stages in one and the same morbid process, but represent rather the different effects of perhaps the same morbid process.

A SERIES OF CASES OF ACTINOMYCOSIS.

BY RICKMAN J. GODLEE, M.S. LOND., F.R.C.S. ENG.,
HOLME PROFESSOR OF CLINICAL SURGERY AT UNIVERSITY COLLEGE, LONDON; CONSULTING SURGEON TO THE HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, BROMPTON.

WHY, it may be asked, should a few more cases of this well-known disease be added at the present time to the already over-burdened literature of actinomycosis? The answer is that it is still thought to be uncommon, and for this reason, and because it very closely simulates some other diseases, it is frequently overlooked. I have myself seen 13, as I think, genuine and two doubtful cases during the last 12 years, though before that time I had not recognised a single one. It is practically certain that this is only a question of having one's eyes opened. Within two years I have myself been treating a case for many months without finding out what was the matter, though I am keenly on the look-out for examples of the disease. I do not believe in the occurrence of new diseases. One cannot fail to be struck with the fact that when a new disease is described cases are promptly forthcoming from all quarters. It seems hardly credible that when I was a student Sir William Jenner used to tell us that no case of floating kidney diagnosed during life had, as far as he knew, been found to be such post mortem, and that he used to demonstrate to us a tumour which he thought was a floating kidney but which, when the patient died, turned out to be a uterine fibroid with a long pedicle. And now where is the third year's student who cannot diagnose one?

I well remember the first case of acromegaly that came before me. The disease had never been recognised in this country before, and as a matter of fact the first two cases were described on the same night by the late Dr. Hadden and by myself. Of course, we had all been seeing cases of acromegaly before, just as we had been seeing cases of osteitis deformans before Sir James Paget told us what it was, or myxœdema before we were taught about it by Sir William Gull and Dr. Ord. And so it is, I have no

doubt, with regard to actinomycosis. A few more years and everyone will be able to recognise it. It will take its proper place amongst other diseases, and, what is of more importance, it will be submitted to early treatment and then it is probable that a larger number of cases will be cured than is possible at present. It is a humiliating thought that we are seeing, but not observing, other forms of disease which will seem quite commonplace to our successors if not to ourselves and, what is worse, that we are treating them wrongly because we do not recognise their true nature.

I do not propose to say much about the organism or organisms that produce this disease, as I think that much confusion is apt to be introduced by, so to say, amateur descriptions. It is also pretty clear that the botanists and bacteriologists have not yet quite made up their minds about the exact affinities of the fungus or fungi in question. It is, however, important for the clinician to know one or two facts about it. And first it is well to know that the word "pseudo-actinomycosis," like the word "pseudo-tuberculosis," has crept into medical terminology. It should suggest to our minds that we may meet with cases presenting all the clinical characters of actinomycosis (I say nothing about tuberculosis) but in which what are recognised to be the characteristic appearances of the fungi are not seen. It is intended, however, to imply that identical, or almost identical, clinical appearances may be produced by separate organisms—a much more doubtful proposition. But we had better leave the botanists to settle whether, after all, the different forms do not belong to the same fungus, for we find them hinting at even wider and more unexpected relationships. It has, indeed, been suggested that streptothrix actinomyces and bacillus tuberculosis may be, as it were, the products of the same plant, in connexion with which the occasional clinical association of tuberculosis and actinomycosis must not be lost sight of.

To the clinician the first sight of the fungus is usually obtained in the pus evacuated from an abscess or in the expectoration, and it is visible to the naked eye as small round granules, sometimes very minute, sometimes larger, oftenest of a pale yellow colour but sometimes white, which are easily demonstrated by allowing the pus or expectoration to flow down the side of the test-tube while it is held up to the light or to run over a microscopic slide. They have been compared to particles of iodoform but they are obviously rounded and not of such a bright yellow colour. One should always be on the *qui vive* and get into the habit of looking at the pus from any abscess of doubtful origin from this point of view, but especially if, on opening the abscess, the amount of pus is less than was expected and the finger passes into an indefinite soft mass which bleeds with great freedom. The sensation imparted to the finger is very characteristic when one is accustomed to it. The hæmorrhage suggests what is the fact, that the growth does not interfere with vessels and is in itself very vascular.

If a yellow granule be placed unstained in a little water on a slide and the cover-glass be gently pressed upon it, it will be seen under a low power to be made up of rounded masses which are yellowish on the circumference but less coloured in the centre. Under a high power the centre is seen to consist of a densely felted mass of threads which is called the mycelium, and the circumference to contain the so-called clubs which, from their radiated arrangement, have given the name to the fungus. In some cases, however, these are not to be seen. It must not be supposed that the mycelium is made up of well-defined threads like the mycelium of a mould or a mushroom. It consists of extremely delicate branched threads in which a double outline is scarcely to be distinguished and which sometimes appear to be made up only of chains of cocci which has suggested the latest name for the organism, "streptothrix actinomyces." We are told that the organism is easily grown on various media and that it then consists at first of these threads, which after some time end in chains of streptothrix, which are supposed to constitute the spores of the fungus. At all events these if transferred to another medium bud out into the threads of the so-called mycelium. The clubs are very seldom if ever produced in artificial cultures. In old cultures bulbous ends to the threads are sometimes observed, and it is held that the clubs are only produced when the organism is growing under difficulties.

Although it is practically certain that the organism grows on cereals and grass very little is known of life-history as a vegetable parasite. It is, however, quite certain that it gains access to the bodies of men and beasts on pieces of corn or grass which either stick in the teeth, or mouth, or are swallowed or inhaled—the moral of which ought to be that we should give up the tempting habit of chewing fresh corn, sucking straws, or putting pieces of fresh grass into our mouths. We cannot help inhaling the dust of a threshing machine and are most likely exposed to the inroads of this pestilent organism in a thousand ways which it is impossible to guard against. Once settled in the mucous membrane of the mouth, œsophagus, alimentary tract, or respiratory passages it begins to grow and creates inflammation. Sometimes an ulcer is produced, sometimes a sort of tumour, and it is usually the latter condition that the surgeon is called upon to treat or the pathologist to examine. The tumour is of a pale yellowish colour, globular in shape, riddled with holes of a larger or smaller size containing pus, and very vascular, although it presents a superficial resemblance to the interior of a tuberculous or gummatous deposit. It infiltrates all the tissues with which it comes in contact, spreading in the intermuscular planes and to some extent into the muscles, extending far and wide into the cancellous structure of bones, occupying extensive portions of the solid viscera, and forming communications between the hollow viscera. It sometimes attacks the skin, sometimes it is met with in the lymphatic glands, and occasionally it is distributed to distant parts of the body by the vascular system exactly as in embolic pyæmia; it is then found in the brain or joints, or, indeed, any part of the body. When it occurs in accessible positions it may be completely eradicated by excision or incision and scraping. When it involves regions beyond the reach of surgery the termination is generally fatal. The only drug which appears to exercise any influence upon it is iodide of potassium, which should be given in large doses, 40 grains or more three times a day. It has been asserted that this is a specific which will cure all cases, but this is not the fact, as the experience of others besides myself unfortunately proves. The practice of trusting to this only if removal is possible cannot, therefore, be too strongly deprecated. A combination of surgery and medicine gives the best prospect of a cure.

The diseases with which actinomycosis is most likely to be confused are tubercle and syphilis. It is fortunate for the patient if it be mistaken for the latter, for under these circumstances it is likely that iodide of potassium will be administered and the surgeon may be—as happened in one of my cases—confirmed in his mistaken diagnosis by the successful result of treatment.

With these prefatory remarks I will pass to the cases that have come under my notice which illustrate most of the commoner and some of the rarer manifestations of the disease.

The first four cases affected principally the pleura.

CASE 1.[1]—A boy, aged nine years, was admitted into the Brompton Hospital for Consumption under Sir Richard (then Dr.) Douglas Powell on Oct. 8th, 1889. His father kept a dairy. There was a history of tubercle in the family. His illness began with languidness in June, 1888. This was followed by pain and tenderness in the right side in August, and then a hacking cough without expectoration supervened. On admission he was pale and anæmic with a hectic temperature. The right side of the chest was enlarged and there were two semi-fluctuating swellings, one in the fifth interspace on the nipple line, the other corresponding to the seventh, eighth, and ninth ribs in the posterior axillary line. The head was held to the right owing to a curve of the spine with the concavity to the right. The physical signs were ambiguous, but they suggested the presence of an empyema pointing at two places. The liver dulness was not increased downwards. As a puncture did not withdraw any pus an incision was made on Nov. 1st and carried through an intercostal space. It entered a soft, friable, yellow mass which bled freely, but no pus escaped. A little hæmoptysis followed. An examination of the material which had been withdrawn showed the fungus of actinomyces. The disease advanced rather rapidly, several fresh openings forming and the swelling increasing to a great extent. The boy became intensely emaciated. The superficial veins became clearly visible over his emaciated body. The liver became distinctly enlarged and he died on Feb. 26th, 1889. At the post-mortem examination the disease was found

[1] Transactions of the Royal Medical and Chirurgical Society, 1889, p. 179.

in greatest abundance in the pleura, from the second rib downwards and extending between the base of the lung and the diaphragm. It involved some of the ribs and the corresponding dorsal vertebræ. There were considerable numbers of nodules of the growth in the lower and middle lobes of the right lung which was tough and fibrous. There were some grey nodules resembling tubercle at the apex of this lung. A few nodules of actinomycosis were found in the left lung. There was a mass of the disease between the liver and the diaphragm and a focus as large as a small orange one inch below the upper surface of the organ. It is impossible to say with certainty where the primary disease started in this case, but we thought at the time it was probably in the pleura. At the time of the operation—i-e., before the matter was examined—I thought that I had incised a vascular sarcoma.

I did not see another case of actinomycosis till 1893. The following one occurred in 1898 and it is reported here as it resembles the preceding case more closely than any other of the series.

CASE 2.—A youth, aged 17 years, was admitted under the care of Dr. Percy Kidd to the Brompton Hospital on August 24th, 1898, complaining of a cough and of a painful swelling in the back. He had always lived in town, but had had a holiday in the country in June, 1897. There was no history of sucking straws or of chewing grass. His cough began about Christmas, 1897, and the swelling in the back was noticed three weeks before admission. He had always been thin. On admission he was a pale thin boy with a slight husky cough and but little expectoration. The notes record physical signs at the right apex strongly suggestive of early tuberculous mischief. There was a large fluctuating swelling between the scapula below its spine and the vertebral column, which interfered with the physical examination of this part of the chest. The temperature varied from 99·5° to 102·8° F. The urine had a specific gravity of 1012 and contained no albumin. On August 30th the abscess in the back was opened by Mr. B. Pollard and about three ounces of thick caseous material were withdrawn. The cavity was then thoroughly scraped with a sharp spoon which gave rise to some bleeding; it was then rubbed with iodoform and the wound was completely sewn up. Mr. Pollard tells me that from the appearance of the case, and perhaps also because he was told that the patient was tuberculous, he thought it was a tuberculous abscess, and was perhaps rather surprised that no deep sinus was found leading down to bone. Though the patient improved somewhat after the operation the temperature did not come down and it is recorded in the notes on Sept. 17th that there is no evidence of re-accumulation in the abscess, but the signs at the apex appear to be extending, which suggests that up to that time the case was supposed to be one of tuberculosis. By the beginning of October the abscess had begun again to discharge, and on the 19th the house physician noticed the characteristic yellow granules in the discharge, and, of course, immediately examined the sputum, in which similar bodies were discovered. It now became obvious that there was mischief in the lung beneath the abscess in the back, and at Dr. Kidd's request I undertook a preliminary operation on Nov. 16th with the intention of opening the lung at a later period. I took out about three inches of the third, fourth, and fifth ribs between the scapula and the spine and stitched the lung up to the parietal pleura. It was quite evident that the soft tissues and the bones were extensively implicated with the disease. There was not much hæmorrhage or shock, but the patient, who was at the time very weak and intensely anæmic, never really rallied from the operation and died nine days afterwards, on Nov. 25th. The temperature varied very little throughout the treatment of the case. At the post-mortem examination all the ribs from the first to the ninth, from the angles to the vertebral attachments, and all the corresponding vertebræ were implicated with actinomycosis, and were so soft that they could be cut with a knife. The pleura was much thickened and nearly the whole of the right lung was involved in the disease. I well remember that at the time of the post-mortem examination it was remarked that the appearances closely resembled those produced by tuberculosis; in fact, that, if we had not known what we were dealing with, they might almost have passed muster as being tuberculous. This is doubly interesting in connexion with the fact that when the patient was admitted the physical signs were considered to be so unequivocal that it was not thought necessary to examine the sputa for tubercle bacilli. Nothing else of importance was found except two or three nodules at the apex of the left lower lobe and a few glands at the bifurcation of the trachea which were neither caseous nor suppurating.

The next case is interesting as an illustration of how a case may be watched by numerous observers (including myself) and its true nature be revealed only accidentally at the post-mortem examination. It is also interesting as being the most rapidly fatal case that I have met with.

CASE 3.—A man, aged 38 years, married, was seen with Dr. W. Thyne of Barnet on Nov. 25th, 1899. His previous history revealed nothing of importance. It is not clear when he first began to be ill, but it was in the spring of 1899. In July Dr. F. T. Roberts diagnosed double pleurisy and the patient was sent to Ilkley. An abscess then formed over the head of the right radius, which was opened. In August the right pleura was aspirated and subsequently it was opened and a tube was inserted. No record of the nature of the fluid can be obtained. After the aspiration an abscess developed over the sternum. The patient returned to Barnet on Nov. 6th, having then a tube in the left pleura and two sinuses, the remains of the abscesses mentioned above. He was very weak and breathless, with a hectic temperature of from 99° to 103° F., and, in spite of a fair appetite, rapidly going down hill. He was seen twice by Dr. Hector Mackenzie who advised further exploration of the chest; but beyond affording somewhat better drainage no good result followed. I saw him on Nov. 25th, but did not see that anything surgical could help him, as it was clear that the cavity in the chest was very small and communicated freely with a bronchus. I was struck by a small square patch of absolute dulness to the right of the sternum but above the liver dulness. The patient became rapidly worse and died on Dec. 7th, the final diagnosis, *faute de mieux*, being empyema followed by septicæmia. Dr. Thyne obtained leave for a partial post-mortem examination and he forwarded to me a hard lump which corresponded to the patch of dulness to which I had drawn attention, saying that it looked like a tumour. This was submitted to microscopical examination and by good fortune a beautiful example of the fungus appeared in the section. Had it not been for this, a correct opinion of the case would never have been arrived at. Whether the disease affected the pericardium or not I cannot say; but it is most probable that it did, such affection being apparently not very uncommon.[2]

Another case which I have met with during the present year illustrates in the same way how easily the disease may be overlooked. It is a much more chronic one.

CASE 4.—A girl, aged 18 years, was sent to me by Dr. W. A. Gostling of Worthing on May 18th, 1900. She was fairly well until 1897, though there were points in her previous history strongly suggestive of tuberculosis. In June, 1897, she had slight hæmoptysis and suspicious signs at the left apex. In August, 1897, there was left pleurisy followed by empyema. This was opened by Dr. Frank Hinds, stinking pus being evacuated. The wound healed and she gained flesh. After six months the matter re-accumulated and for the next two and three-quarter years the wound opened and closed periodically, although Dr. Hinds had effected better drainage at a second operation by removing a piece of rib. Indeed, she had worn a tube for about half this prolonged period of time. For six weeks before I saw her there had been some fever, the temperature being from 99° to 101° F., but before that for a long time the temperature had been normal. She lost flesh and became very ill, and a large rounded and very tender tumour appeared in the left side of the abdomen; it was quite dull and was evidently incorporated with the abdominal wall. There were no physical signs at the left apex. I thought that it was probably a tuberculous empyema and that the abdominal swelling was an abscess burrowing down in the abdominal wall from the pleura; but the alternative diagnoses of tuberculous peritonitis or of caries of the spine were discussed. An incision into the tumour at once revealed the true nature of the case. The free hæmorrhage, the small amount of matter burrowing amongst the abdominal muscles and deeper parts, and the indefinite spongy surroundings of the abscess made us immediately examine the pus, and before the completion of the operation a typical specimen of the clubs was shown under the microscope in the theatre.

[2] Cf. Sir Dyce Duckworth: A Case of Acute Actinomycosis, Transactions of the Clinical Society of London, Oct. 12th, 1900.

The patient was put on large doses of iodide of potassium, taking as much as 40 grains three times a day, to which she at once responded. On a subsequent occasion the sinuses were again thoroughly scraped and before many months the wound had healed. She is now apparently well and has grown plump and strong, but there is still some induration beneath the abdominal scar and until this has disappeared I suppose we cannot say that the disease is completely eradicated. For this reason she is continuing to take the iodide of potassium.

The following six cases appear to have originated in the liver.

CASE 5.—A man, aged 45 years, was admitted into University College Hospital on March 5th, 1896, under the care of Dr. G. V. Poore. He had been ill since August, 1895, when he became unaccountably weak and breathless. He lost flesh and perspired at night. The appetite failed and presently a red patch appeared of about the size of the palm of the hand over the lower ribs on the right side. On Sept. 28th he was told that he had an abscess of the liver, and a few days later about four pints of offensive brown pus were evacuated from the abscess. He had coughed up about a pint of a similar material on the night before the operation. Five weeks after the operation he thought he was quite well. In December, however, he began to feel ill again and was taken to see the late Dr. George Harley who is reported to have said that he had diseased bone. He continued to get weaker and to be much troubled with cough up to the time of his admission, when he was obviously very ill. He was emaciated and had an anxious expression. There was a certain amount of bulging of the lower ribs on the right side and there was a sore covered with exuberant granulations in the mid-axillary line over the eighth rib. In the centre of this was a sinus into which a probe passed in various directions for about an inch, but no bare bone was felt. There was slight scoliosis, the concavity being to the right side. The movements of the lower part of the right side of the chest were much impaired and there was slight dulness at the right base, but nothing very marked. There was no apparent enlargement of the liver, which indeed could not be felt below the costal margin. The temperature was of a markedly hectic type, ranging from 99° to 103° F., and with slight variations it remained so until the end of the case. The urine presented no abnormalities. No diagnosis was made at first, though empyema was suggested; but when I was asked to see him (on March 9th) the characteristic yellow granules in the yellow pus escaping from the sinus at once explained the case. He was put upon iodide of potassium, the dose of which was rapidly increased to 25 grains three times a day, but he did not bear it well, and on March 29th it was discontinued. It was again given in smaller doses and was continued at intervals, as the patient could bear it, till the end of the case. Small doses of nitrate of silver were also administered at Dr. Poore's suggestion, and nitrate of silver was applied to the granulations, but no appreciable effect resulted from the treatment. On April 11th I removed all the superficial structures which were affected, and finding that the eighth and ninth ribs were involved I removed considerable portions of them and scraped, as far as I could, the cavity which appeared to be a part of the pleura beneath them. The case went rather rapidly from bad to worse. There were very troublesome diarrhœa, great emaciation, and an exaggeration both of the ascents and descents of the hectic temperature. The wound was scraped on several occasions, and various external applications such as iodine, iodoform, nitrate of silver, sulphur, and formalin were employed, but without effect, and the patient died on June 3rd. At the post-mortem examination a large mass of typical actinomycosis three inches in diameter was found in the right lobe of the liver, the oldest part of which was apparently below and was very closely adherent to the hepatic flexure of the colon which, however, showed no sign of ulceration. Extending upwards from this was a cavity partly between the liver and the lung and partly in the lung itself. The middle and lower lobes of the right lung were surrounded by a very much thickened pleura. Some ordinary pyæmic abscesses were found in the left lung and one in the anterior horn of the lateral ventricle of the brain on the left side.

CASE 6.—A man, aged 22 years, was admitted into the Brompton Hospital under the care of Dr. Kidd on Feb. 21st, 1899. He had been a healthy man up to six months previously when he had had an attack of diarrhœa which lasted three weeks accompanied by pain in the abdomen. He then remained well for three months when he had an attack of pleurisy on the right side. He was very ill for six weeks and from that time he began to cough and expectorate and was troubled with shortness of breath. On admission the patient was evidently very ill, with a hectic temperature varying from 98° to 102° F., with physical signs that appeared to indicate the presence of fluid at the right base, and some œdema of the legs. The urine had a specific gravity of from 1022 to 1025 and contained a thick cloud of albumin and hyaline and granular casts. Neither the liver nor the spleen could be felt, but the latter became obviously palpable in the course of a few days. A fluctuating swelling made its appearance over the left great trochanter, and there were three or four small round nodules in the skin of the forehead and scalp which felt very much like sebaceous cysts. The diagnosis of this case was very doubtful, though it was recognised that there were some serious renal mischief and fluid in the right pleura. On March 20th—a month after admission—the abscess over the great trochanter was aspirated and some iodoform emulsion was inserted. On the 25th I was asked to see him and found a large abscess in front of and around the hip-joint, the movements of which did not appear to be more impaired than the presence of this large collection of pus in its neighbourhood would account for. On incising it a large quantity—a pint or more—of brown pus escaped, in which we at once detected the granules of actinomycosis in great abundance. Even if I had not been on the look-out for them the character of the abscess as determined by the insertion of the finger would have made me almost certain of the diagnosis. The indefinite spongy walls, easily breaking down before the finger in all directions and bleeding very freely, are almost unmistakeable when they have been felt two or three times. The abscess did not appear to communicate with the hip-joint, but passed up towards the abdomen. The day after the operation (March 26th) the patient had two attacks of convulsions followed by loss of power on the left side of the body and accompanied by unconsciousness. On the 28th there was a similar but more severe attack. From this time he gradually took less notice and became less and less conscious. He had some more attacks of convulsions and there was some paresis of the left side. He evidently had some headache and there was some vomiting. The swellings in the scalp increased very much in size. The temperature retained its hectic type till April 4th and then was subnormal till the time of his death on the 10th. At the post-mortem examination a great variety of lesions were found, indicating apparently that the disease had become diffused throughout the body by a process of embolism such as occurs in embolic pyæmia. The largest and most obvious focus of disease was a globular mass as large as a fœtal head in the right lobe of the liver. It was therefore assumed that this was the seat of the primary lesion, but this was of course only a surmise. There was also a smaller nodule in the anterior part of the liver. The large mass extended up to the diaphragm which was intimately adherent to the liver and was invaded by the disease. The posterior quarter of the right lung was adherent to the chest wall and the mischief had extended up into the adhesions, involving as well the corresponding ribs and intercostal spaces (from the eighth to the twelfth) from the spine to the angles of the ribs, but neither the vertebræ nor the ribs were obviously softened. At the extreme base of the right lung there was a limited infiltration of small caseous nodules surrounded by broncho-pneumonia. In the outer part of the cortex of the right kidney there was a nodule of the disease of the size of a pea. A large suppurating gland on the bifurcation of the trachea had ruptured into that tube, and it was no doubt the source of the fœtid expectoration noticed before death. A careful examination was made of the abscess about the hip-joint. It extended widely into the intermuscular planes, but no communication with the joint could be discovered. The joint, however, contained a considerable quantity of semi-gelatinous puriform material, but as this was not collected with sufficient care to ensure that there was no admixture of pus from the surrounding abscess I cannot say whether or not it contained any of the fungus. A somewhat similar gelatinous material was found in the left knee-joints and the left metatarso-phalangeal joint of the big toe. Two circumscribed collections of pus beneath the peritoneum were also found, one immediately above the bladder in the recto-vesical pouch, the other in

the gastro-splenic omentum. Several superficial abscesses were also found. Some of them were the nodules noticed during life in the scalp; one was situated over the metatarso-phalangeal joint of the great toe of the right foot. Several abscesses of considerable size were found in the cerebral hemispheres; one large and two smaller ones were in the left frontal lobe and there was on each side further back a large abscess, that on the right side approaching the surface of the brain in the centre of the ascending parietal convolution. All the collections of pus, with the possible exception of that from the left hip, contained the fungus.

This case is one of the most instructive of the series, not only because it remained so long undiagnosed though under daily and careful observation, nor because even after it was diagnosed the extent of the lesions was not suspected, but chiefly because it illustrates so well the diffusion of the disease to distant parts of the body by means of the blood-stream. It is further interesting to note that although the secondary abscesses were met with in the brain, the skin, and the intermuscular planes the affection of the lung was very limited. The affection of the lung appeared to be by direct extension and there were none of the characteristic abscesses of embolic pyæmia in it.

CASE 7.—A youth, aged 17 years, was admitted into the Brompton Hospital under the care of Dr. Kidd on Nov. 18th, 1898. He is said to have been in good health until the present illness started with cough and pain in the right side about six weeks before his admission. He was stunted, pale, anæmic, and rickety. The left side of the chest was normal, except that the heart's apex was slightly displaced outwards. The right side bulged; it was dull throughout behind, and below the fourth rib in front, the breathing in the dull part being very weak and accompanied by râles. Expectoration was slight and purulent. The liver dulness extended one and a half inches below the margin of the ribs. There was frequent diarrhœa, though he had been constipated before admission. There was no albumin in the urine. The chest was explored without result, and on Dec. 4th the patient expectorated a collar stud. We thought at this time that he must have some bronchiectasis caused by the presence of the foreign body, but that probably there was a malignant growth as well. The temperature, which on admission varied from normal to 101° and 102° F., fell to nearly normal after the expectoration of the stud and remained so for many weeks. The patient walked with a marked stoop to the right because his spine was curved, as is usual, with the concavity towards the affected side. The disease steadily advanced and the boy became much weaker. In February the side became tender and a prominence appeared over the sixth rib on the right axilla, which was incised on Feb. 20th. No bare bone was felt but a track passed through an intercostal space into some internal cavity. There was very free hæmorrhage but very slight hæmoptysis after the operation. On April 18th an exploring trocar was passed through the eighth intercostal space in the mid-axillary line and, as pus flowed pretty freely, an opening was made which admitted the finger, as at the last operation, into a spongy honeycombed part of what I took to be the lung infiltrated with pus, but not in any large quantity. There was free bleeding, but not a trace of hæmoptysis followed the operation. I noted that this was very puzzling, as I could not think that I had penetrated the liver. By this time the liver had become very large and hard, the abdomen was distended and probably contained fluid, and there was a good deal of albumin in the urine. A needle was passed into the prominent part of the liver at the epigastrium but no pus was discovered. The patient rapidly became worse; emaciation was extreme and the superficial sinus became very obvious. The temperature rose and assumed an irregularly hectic type. There were some rigors and there were obvious signs of peritonitis over the liver and of fluid in the abdomen. The wounds showed a tendency to heal superficially, but on one occasion there was an escape of orange-yellow pus from one of them. He died on May 7th. At the post-mortem examination the base of the right lung was found to be everywhere adherent to the diaphragm, as also was the upper surface of the right lobe of the liver. The upper surface of the liver was separated in places from the diaphragm by small abscesses filled with creamy pus, one of which communicated with the opening which I had made in the fifth interspace, and another with the incision in the seventh interspace. No communication could be found between these spaces and the liver, but the liver substance beneath them was occupied by softened caseous, and in some places suppurating, cavities. The whole of the right lobe of the liver except the lower two and a half inches was riddled and honeycombed by caseous areas and suppurating cavites of various sizes, the cavities being obviously formed by the breaking down of the caseous masses, as they were lined by a similar yellow caseous material. A similar change was found in the upper half of the left lobe. The portal and hepatic veins were healthy, as also were the gall-bladder and bile ducts. The only other morbid appearance of importance met with was in the right lung, the lower lobe of which was in a state of condensation due to collapse, the bronchi being dilated. There was, however, no appearance of any change which could be attributed to actinomycosis.

The interest of this case depends upon the following facts. 1. The incisions which were always thought to have penetrated the lung really opened cavities between the diaphragm and the liver. It was, however, noticed on each occasion that little or no hæmoptysis followed and the small amount of discharge and the tendency to heal were remarked at the time. 2. We were at the time keenly on the look out for cases of actinomycosis, and I several times said that it could hardly be anything else, but repeated examinations of the pus failed to detect the fungus. 3. This is explained by the fact that the mycelium was more delicate than usual and that the fungus did not present the typical clubs; but on this point I will say no more as Dr. S. H. Habershon has described the appearances met with in this case.[3] It leads, however, to the remark that the clubs are not always met with even in cases in which they have at one time been easily demonstrated. I do not mean in cases that are recovering; that is, of course, what one would expect. In two at least of my series—Case 5 and Case 12—which terminated fatally and in which there was no lack of discharge it became more and more difficult and was at last impossible to discover any clubs at all, although they were seen in abundance during the earlier part of the disease. I would observe that if post-mortem room or museum specimens are found which to the naked eye look like the disease but in which no fungus is found it will not do to state positively that the case has not been one of actinomycosis.

CASE 8.—A girl, aged 15 years, was admitted into the Brompton Hospital under the care of Dr. J. K. Fowler on June 2nd, 1893. She had been suddenly seized a fortnight before with headache, vomiting, and severe pain in the right side. The pain was worse on drawing a deep breath, and she had slight shivering. On admission she had a cough and there was some slightly blood-stained expectoration. She was not anæmic or emaciated. The tongue was slightly coated. She had a hectic temperature varying between 101° and 104° F. and a very rapid pulse. The urine was normal. There were signs of fluid at the right base, but nothing abnormal was detected in the abdomen. On the 14th I opened the right pleura after excising a portion of the ninth rib in the scapular line and after passing through quite an inch of dense pleura a large cavity was reached which extended forwards for a considerable distance. We made no diagnosis of this case though numerous suggestions were made. The subject of actinomycosis was not so present to our minds as it is now. The patient was in no way relieved by the operation, but she became rapidly emaciated and intensely anæmic. The temperature remained the same till a few days before the fatal termination, which occurred from exhaustion on August 1st—that is, two and a half months after the first onset of the symptoms. At the post-mortem examination it was found that the posterior part of the right lung was firmly adherent to the chest wall from apex to base except at two places, one above (from the second to the fourth ribs) and one at the lower part. The upper of these was a localised abscess containing an ounce or two of thick creamy pus; the lower led by means of a sinus through the diaphragm into a large yellow caseous mass in the right lobe of the liver, measuring four inches vertically by three from side to side and two from before back. It closely approached the upper and anterior surface of the liver which was adherent at these parts to the diaphragm. There was a mass of caseous and calcareous glands at the bifurcation of the trachea. There was no tubercle in the lungs. The middle and lower lobes of the right lung were collapsed and carnified, a result no doubt of the empyema. Nothing else of importance was noticed at the post-mortem examination.

This case created considerable interest at the time. At

[3] Transactions of the Pathological Society of London, Nov. 8th, 1900.

first it was thought that it might be one of typhoid fever, but that idea was abandoned. No suspicion of an affection of the liver occurred, I believe, either to Dr. Fowler or myself. And at the post-mortem examination (at which I was not present) it was suggested that the mass in the liver was probably caseous tubercle. It was only on looking at the specimen afterwards and comparing it with the other cases that had occurred that the idea occurred to the resident medical officer of searching for the fungus. He discovered some spots containing what appeared to be mycelium, but it must in fairness be added that there is no microscopical proof of the conclusion to which the naked-eye appearances would seem to lead.

CASES 9 AND 10.—Two other cases must be briefly mentioned because, though I am personally convinced that they were examples of the disease, I have no actual proof of the fact. They both occurred at University College Hospital and I cannot find the notes of either. In both the liver was the seat of the mischief. One of the patients was a man, aged 26 years, and the other was a girl, aged 14 years.

In the next three cases some part of the intestine was affected.

CASE 11.—A man, aged 29 years, was admitted under my care into University College Hospital on March 18th, 1895, on account of a swelling in the right groin. He said that he had been healthy till 10 weeks before his admission, when he began to suffer from a dull aching pain in the abdomen, which gradually got worse, and after a week he was obliged to take to his bed. He then became very constipated and was obliged to resort to enemata. The constipation then passed off and the pain diminished, but he kept his bed for six weeks, after which he began to get about again. Soon, however, the pain returned and settled in the right hip, so that he again had to take to his bed and was sent by his medical attendant to the hospital. He looked then rather ill, and was slightly wasted. His tongue was furred and he had on the first night a temperature of 103° F. It had fallen to 100·2° by the next morning. His right thigh was flexed to an angle of 75 degrees, and there was evidently a large abscess in the right iliac fossa. It reached to within two inches of the symphisis and extended one inch below Poupart's ligament, but did not reach up into the loin. It was hard and painful but not tender. The urine was normal. I opened the abscess on the 20th by an incision one and a half inches internal to the anterior superior spine. It was apparently extra-peritoneal and contained a considerable quantity of feculent-smelling pus containing actinomyces. A large drainage-tube was inserted. The patient was put upon iodide of potassium and before long he took 40 grains of it three times a day, which he continued to do during the treatment of the case. The wound improved, but it was thought right to open it up and scrape it on three subsequent occasions. On May 25th he left the hospital convalescent and he returned afterwards with the wound completely healed. With few exceptions the temperature remained about normal; on one occasion it reached 101·8° and for a few days before he left the hospital the evening temperature approached 100°.

CASE 12.[1]—The patient was a man, aged about 30 years, whom I was asked to see by Dr. Fairbrother. He had previously been in good health. In 1893 he had at intervals of three months attacks which suggested appendicitis. In February, 1894, there was a still more definite attack of the same nature. In May, 1894, after a similar attack, a swelling appeared which occupied the right lumbar and iliac regions and there was obvious suppuration in the posterior part of it. I opened the abscess at this part and was impressed by the small amount of pus and the very free bleeding. I thought that it was probably a perirenal rather than a perityphlitic abscess, but I did not at that time guess its true nature. On seeing him three weeks afterwards, however, I was struck with the fact that the matter was burrowing in the subcutaneous tissues and inter-muscular planes and took some of it away for microscopical examination and found it teeming with the actinomyces. Afterwards the abscess pointed in front and I again opened it and scraped it, the hæmorrhage at this operation being alarming. The abscesses burrowed in various directions and the patient became intensely anæmic and emaciated in spite of the methodical administration of iodide of potassium and iodide of sodium and the constant irrigation of the sinuses with tincture of iodide. He died on Feb. 25th, 1895, and at the post-mortem examination it was found that the appendix had probably been the original source of the disease. Sinuses passed in many directions, but there was nothing at the time of death in the appearance of them to indicate that they were the result of actinomycosis. This is a most interesting observation because it may explain how cases may not only pass through the whole period of treatment without recognition, but may be examined by competent pathologists on post-mortem examination without any hint being obtained as to the true nature of the affection.

CASE 13.—A boy, aged 16 years, was admitted into the Brompton Hospital under Dr. Fowler on June 22nd, 1898, complaining of pain in the chest and abdomen and a lump in the left iliac region. His illness commenced in August, 1897, with sharp pains in the chest and abdomen which lasted three weeks and were attributed to acute indigestion. He then remained well until Christmas, 1897, when he was suddenly taken with vomiting which lasted off and on for 14 hours. After that the bowels were constipated for a week but were relieved by enemata. He then returned to work until a month before his admission into the hospital, when he was again seized with pains in the abdomen which laid him up for two or three days, since which time the pains had gradually become worse. Nothing abnormal had at any time been noticed with the motions. For a few days before admission he had observed that he could not straighten the left hip. He was a pale, anæmic boy, whose trouble was evidently abdominal, and it was at first supposed that he had some form of obstruction of the bowels. A very obvious lump was to be felt in the left iliac fossa and also per rectum. It extended as far back as the posterior third of the iliac crest and forwards to within one and a half inches of the spine of the pubes, and when I first saw him on June 27th distinct fluctuation in the swelling was to be obtained. In fact, the case was obviously one of abscess, and naturally a psoas abscess was suggested, but there were no signs of caries of the spine. The temperature varied between 100° and 102° F. The urine was normal. On June 27th I made an incision into the abscess and found that it extended up into the loin and down into the pelvis. It was extra-peritoneal but superficial to the iliacus muscle. It had, however, stripped the vessels away from the iliacus so that they came to be in the anterior wall of the abscess. The bleeding was considerable, but not enough to be dangerous. The pus was yellow and contained white particles in which the mycelium of actinomyces was seen without staining and in which the clubs were brought out on staining by Gram's method. He was at once given iodide of potassium, at first in five-grain doses three times day. By August 15th he was taking 15 grains and by the 30th 25 grains three times a day. The operation was followed by a lowering of the temperature to about 99°, at which it remained for 10 days or more. It then gradually resumed an irregularly hectic type, seldom, however, rising above 101°. At first there seemed to be some slight improvement, but the patient remained very anæmic and though at first he put on weight he afterwards became more and more emaciated. On Sept. 18th, the wound was opened up under chloroform by Mr. Pollard and scraped and iodoform was rubbed in, and on the 16th a swelling which had formed on the left side of the lumbar spine was similarly treated. No communication was found between this and the abscess in the groin. On Dec. 1st fæces were discharged through the wound in the groin and on the 12th there was a similar discharge from the wound in the back. This continued until the patient's death on the 21st. He had in the meantime become gradually weaker, but no other symptoms had developed. At the post-mortem examination it was found that the sinuses led to an extensive abscess which surrounded the rectum and led up alongside the sacrum, involving the sacro-iliac articulation of the left side, the coccyx, and the lowest four sacral vertebræ, as well as the disc between the sacrum and the fifth lumbar vertebra. It then tracked up the left side of the spine, involving the tissues in the neighbourhood of it but not the lumbar vertebræ, and extending as high as the ninth left rib. The dorsal vertebræ from the ninth to the twelfth were slightly eroded, and the corresponding ribs were slightly involved in the disease. The perirectal abscess contained fæces. All the viscera contained in the pelvis were matted together by old peritonitis, and the sigmoid flexure was coiled upon itself and drawn up to the right. At its lower part behind it was

[1] Reported in the Brit. Med. Jour., June 27th, 1896.

adherent to the abdominal wall, and here there was a large shallow ulcer exposing the muscular coat which presented no peculiar appearances. It was perforated in the centre, the opening communicating with the abscess. There were three small openings with yellow softened edges by which the abscess communicated with the bladder. The body was extremely emaciated, but beyond marked amyloid disease of the liver and spleen it presented no other abnormal appearances.

In the last two cases the mischief occurred in one in the face and in the other in the neck.

CASE 14.—A woman, aged 27 years, a patient of Dr. D. A. Davies, who was sent to me by Dr. J. Mitchell Bruce, was admitted to the hospital in December, 1894. She came of a highly tuberculous family and had tuberculous disease at the apex of the left lung. A year previously the teeth had been stopped and at that time there was great swelling of the face. She thought that she went to the dentist because of a slight toothache and not because of any ulcer of the gums. The swelling of the face was present before she went to the dentist, but it increased very much afterwards. The stoppings were therefore removed and the nerve was killed, and ultimately, six weeks before I saw her, the left canine, two bicuspids, and the first molar of the upper jaw were removed. The swelling broke on the surface of the cheek and discharged from time to time and when she came to London there were two or three openings in the indurated tissue of the left cheek from which exuded pus in which Dr. Bruce at once detected the characteristic yellow masses of actinomycosis. The patient lived outside Swansea and was very fond of chewing corn and straw. I scraped the cheek with great thoroughness on Dec. 17th. The only place that gave any trouble from hæmorrhage was the outside of the upper jaw above the place whence the teeth had been removed, and this very soon stopped. The wounds were plugged with lint soaked in pure carbolic acid. She was at once put on iodide of potassium, being given five grains three times a day, and the wounds rapidly healed. The ominous note was made when she left that there were tubercle bacilli but no actinomyces in the expectoration. She died from pulmonary tuberculosis and rectal fistula some months afterwards; there was no return of mischief in the cheek.

CASE 15.—A woman, aged 33 years, was brought to me on June 18th, 1898, with a swelling near the angle of the jaw, apparently involving the sterno-mastoid. It was very hard, red on the surface, and it involved the skin. She had first noticed pain in the autumn of 1897, which gradually got worse, and the swelling appeared in February, 1898. She had had all the teeth of the upper jaw removed, but I discovered no evidence that they could have had anything to do with the disease. She had had no sore-throat. She had lived on a farm and was very fond of chewing grass and corn. The swelling did not look exactly like a tuberculous gland, but I thought it probable that it was one. It was opened on June 18th and I was much astonished to find that it had all the appearance of a gumma involving the sterno-mastoid, so I cut and scraped away as much as I could and made a careful microscopical examination of a part of the tissue removed. It showed simply inflammatory tissue and on examining the section now I can find no trace of the fungus. I accordingly put her on a course of iodide of potassium and, as I expected, the wound slowly but soundly healed. After stopping the iodide, however, two small nodules appeared at the lower part of the scar and a minute opening occurred at the extreme lower part, after which these nodules disappeared. Another nodule, however, appeared soon afterwards in the middle of the scar and, now being on the look-out, I carefully examined what came away and at once detected some yellow granules which showed typically the fungus of actinomyces.

This is perhaps the most instructive case of the whole series because the true nature of the disease was not recognised for a long time, but the treatment was appropriate though founded on an incorrect diagnosis.

I may point out that of these 15 cases 10 of the patients were males and five were females. Their ages were respectively nine years, 14 years, 15 years, 17 years, 17 years, 18 years, 22 years, 25 years, 26 years, 27 years, about 30 years, 33 years, 38 years, and 45 years. In four cases the lungs and pleura were principally affected; in six cases the liver and pleura were principally affected; in two cases the cæcum or appendix was principally affected; in one case the rectum was principally affected; in one case the jaw was affected; and in one case the neck was affected. The occupations of the males were as follows: one was the son of a dairyman, two were clerks, one was a florist, one was a butcher, one was an errand boy, one was a gentleman, one was a cellar-boy, one was a bricklayer, and one was a railway porter. Of the females there is nothing to be said about the occupation. Four of the 15 recovered, although one died subsequently from pulmonary consumption, and one has had a relapse but is now well. The others all died although several of them were treated vigorously with iodide of potassium. Three had embolic abscesses in the brain or in other parts of the body.

With regard to treatment I would again emphasise the necessity of carrying out active surgical treatment as well as of administering iodide of potassium. How active this treatment should be must be decided according to the merits of each case. I have not yet met with a case in which such an extensive operation as removal of the cæcum offered any chance of success—except, indeed, in one who recovered after the adoption of milder measures. But the inveteracy of the disease and the fact that this operation has once at all events been successfully performed would, I think, warrant its performance under favourable circumstances. The appearances seen in the lungs and liver of several of the cases that ended fatally do not encourage one to attempt much active surgery when these organs are attacked.

The special points which this paper brings out are the following. 1. The probability that this uncommon disease may be mistaken for others of everyday occurrence. 2. The possibility that for long periods and even after death no signs of the ray fungus may be present in the discharges or discoverable in the tissues. 3. The characteristic appearances of the abscess when opened. 4. The possibility of true embolic pyæmia resulting, the secondary abscesses containing the ray fungus. 5. The fact that if the liver or lungs are affected a lateral curvature of the spine is likely to occur, the concavity being towards the affected side.

I must conclude by expressing my sense of obligation to the physicians who have kindly allowed me to describe the cases which in many instances were previously, and in some instances continuously, under their care in hospitals. In the foregoing descriptions I have frequently made use of the plural "we" when the singular pronoun "I" might have been expected. This refers to occasions when questions of diagnosis were discussed between us, and I trust that I have in no case misrepresented the opinion of any of my colleagues.

I also desire to point out to anyone who may consult this paper for the sake of collating cases that some of them have been previously published, one by myself, and others by other writers. In each case, where I am aware of the fact, such previous publication is indicated in the text.

THE AFTER-RESULTS IN 40 CONSECUTIVE CASES OF VAGINAL HYSTERECTOMY PERFORMED FOR CANCER OF THE UTERUS.[1]

BY ARTHUR H. N. LEWERS, M.D. LOND.,
OBSTETRIC PHYSICIAN TO THE LONDON HOSPITAL.

THE series of 40 cases recorded in this paper includes all the cases in which I have performed vaginal hysterectomy for cancer of the uterus up to the end of April, 1899, when I completed my fortieth case. Up to the year 1893 I had for the most part treated cases of cancer of the cervix that appeared suitable for operation by the supra-vaginal amputation of the cervix, and reserved total extirpation of the uterus for cases of primary cancer of the body of the uterus. Since that time, however, I have been more and more convinced that to perform the supra-vaginal amputation of the cervix in such a way as to give the patient the utmost chance that the disease will not recur is, in the majority of

[1] A paper read before the Royal Medical and Chirurgical Society on Nov. 13th, 1900. The author is much indebted to the Council for permission to publish the paper and some of the illustrations before they have appeared in the Transactions of the Society.

cases, a more difficult matter than to perform the operation of vaginal hysterectomy. I have for some time past only performed the supra-vaginal amputation of the cervix for very early cases of cancer of the vaginal portion in which there is a limited and superficial growth. Up to April, 1899, I have had 33 cases of the supra-vaginal amputation of the cervix for cancer, but I do not propose to deal with these cases in this paper.

THE CASES THAT REMAIN FREE FROM RECURRENCE.

Among the 40 cases of vaginal hysterectomy there are 14 cases in which the disease has not recurred. In two of these, Cases 3 and 4 in the series, although the clinical evidence convinced me that they were really examples of cancer, this cannot be proved by examination of the specimens. In the remaining 12 cases there can be, I think, no doubt whatever on this point. The specimens have been carefully examined and are here for inspection to-night, as also are sections of the growth in each case. This appears to me an important point.

My object in the present paper has been to inquire more especially into the *after-results* in the cases of cancer of the uterus in which I have performed vaginal hysterectomy. In such an inquiry it is essential, first of all, to prove that in those cases in which the disease has not recurred the growth was really malignant. In order to satisfy this condition I have in each case had an independent report on the growth by Mr. Targett of the Clinical Research Association, and his report will be found verbatim in the account of each of the cases. The necessity of a careful microscopical examination of the growth in each case is almost self-evident, and when the microscopical examination confirms the opinion based on the clinical features and physical examination there can, I think, be no hesitation in accepting the result as fully proved. In three cases in this series, Cases 3, 4, and 25, the microscopical examination did not confirm the diagnosis of malignancy based on the physical examination. In Cases 3 and 4, though I have excluded them as "non-proven," I feel little doubt that they were cases of cancer. I have myself met with an example of cancer of the cervix in which the appearance of the growth under the microscope would certainly not have warranted a diagnosis of cancer, but in the case in question, one treated by the supra-vaginal amputation of the cervix, the malignant nature of the growth was proved by recurrence. As regards Case 25 in this series, the clinical features and the physical examination led me to believe without any hesitation that the case was one of malignant ulcer of the cervix, but on examination of the cervix by the microscope Mr. Targett reported that the case was one of tuberculous ulceration. To make quite certain he examined two portions, each taken from a different part of the cervix. I think this case is an important one, as clinically it exactly resembled one of cancer of the cervix. Tuberculous ulceration of the cervix as a primary condition must be extremely rare. Very little is to be found about the subject in works on gynæcology, and it has not been regarded as a condition ever likely to give rise to difficulty when the diagnosis of cancer is being considered. Yet in my case (Case 25) primary tuberculous ulceration of the cervix produced a condition identical, as far as physical examination was concerned, with that resulting from malignant ulceration. I have seen a very large number of cases of cancerous ulcer of the cervix, certainly some hundreds, and I am sure that in the case in question the clinical features of the cervix were precisely similar to those produced by the ulceration of a cancerous growth. The occurrence of such a case emphasises the importance of always examining growths supposed to be cancer under the microscope before accepting them as really malignant. Again, one has occasionally heard of a case pronounced by a competent authority to be one of cancer of the cervix where after a long time the patient gradually improved and ultimately made a good recovery, to the surprise of everyone connected with the case, and no doubt to the discredit of the gynæcologist who had made the diagnosis. It seems to me, in the light of the case above referred to (Case 25), that not improbably the patients in some such cases may have really been suffering from tuberculous ulceration of the cervix, which presumably may occasionally get well spontaneously. However that may be, in Case 25, believing it to be a typical example of cancer of the cervix, I performed vaginal hysterectomy and the patient remains quite well. It is more than four years since the operation but I have, of course, excluded the case from Table II.—the list of cases proved to be cancer of the uterus and treated by vaginal hysterectomy which remain free from recurrence at the present time.

To return to the question of the after-history of patients suffering from cancer of the uterus and treated by vaginal hysterectomy, in addition to proving the malignancy of the growth in each case there is the necessity of ascertaining the state of the patient after the operation. It is not an easy thing to do. To have any real value inquiries have to be made from time to time over long periods; for instance, two cases in this paper have been kept under observation for more than seven years. The evidence of non-recurrence may be obtained either by actual vaginal examination or by seeing the patient at intervals and observing that she continues in good health, or by hearing at intervals from her medical attendant that she continues well, or in some cases by hearing from the patient herself at intervals that she continues well. No doubt the most satisfactory thing is to examine the patient; in eight out of the 12 cases in Table II. I have myself examined the patients from time to time. In some cases, however, when the patient continues well she may not be unwilling to come to see you, but she will object to be examined, as she has nothing the matter. Two cases (Cases 7 and 24, Table I.) are in this category. In some cases one can only hear by letter from the patient or from her medical attendant from time to time. This evidence is not so unsatisfactory as it might appear, and for this reason; in those cases in which recurrence takes place the downward progress to a fatal issue is generally fairly rapid—a matter of months, so that if inquiries made at long intervals—once a year, for instance—result in a favourable report there can be no reasonable doubt that the disease has not recurred.

Numerous cases of vaginal hysterectomy and series of cases of vaginal hysterectomy for cancer have been published from time to time; but I am not aware of any considerable series of such cases in which the proof both of the malignancy of the growth, and especially of the condition of the patients many years after the operation, has been given so rigorously and in such detail as in the present series of cases. As regards the after-histories especially, it will be seen that I have given the date on which I either examined the patient or saw her without examining her, or heard from herself by letter, or heard from her usual medical attendant by letter.

As regards the intervals that have elapsed since the operation without recurrence in the 12 cases referred to.—In Case 7 more than seven years have passed and the patient is known to be well, and in Case 8 seven years have also passed without recurrence. Both of these cases were examples of primary carcinoma of the body of the uterus. In Case 15 six years passed without recurrence; in Case 19 five and a half years; in Case 23 five years; in Case 24 nearly five years; in Case 26 nearly four years; in Case 29 more than three years; in Case 32 two years and 10 months; in Case 33 two and three-quarter years; in Case 36 more than two years; and in Case 39 more than one year. Omitting Case 39 it will be seen, therefore, that there are 11 cases out of the 40 remaining free from recurrence from two to seven years after the operation—that is, 27·5 per cent. This result appears deserving of close attention, since at the present time some gynæcologists have been so much discouraged by their experiences as to doubt if it is worth while to operate on cases of cancer of the uterus at all.

The comparatively high percentage of patients remaining free from recurrence in my series is, I believe, largely due to the careful selection of cases. My practice has been generally to examine the cases carefully under anæsthesia and only to operate when the disease has appeared, so far as physical examination can decide, to be limited to the uterus.

As regards the cases in which recurrence is known to have taken place.—The disease is known to have recurred in 18 cases. In 12 of them recurrence took place during the first year; in two during the second year; in two during the third year; and in two during the fourth year. The 40 cases may be divided into groups as follows. In 12 cases there has been no recurrence; in 18 cases there has been recurrence; four patients died; in two cases the nature of the disease cannot be proved by examination of the specimens; in three cases I have no definite information as to whether the disease recurred or not; and in one case the disease proved to be primary tuberculous ulceration of the cervix and not

TABLE I.—40 CONSECUTIVE CASES OF VAGINAL HYSTERECTOMY PERFORMED FOR CANCER OF THE UTERUS.

Case.	Disease.	Date of operation.	Immediate result.	Remarks.	Years of age.	Remote result.
1	Cancer of body.	March 1st, 1886.	Recovered.	Ligatures only used to secure broad ligaments.	58	Recurrence early in 1887. Died July 7th, 1887, 15 months after operation. Recurrence during the first year.
2	Cancer of cervix.	Oct. 4th, 1886.	Died 48 hours after operation.	Pus set free in the operation (pyometra). Wall of right ventricle very thin and heart fatty. Died from œdema of lungs and heart failure. Ligatures only to broad ligaments.	62	—
3	Cancer of body.	Nov. 7th, 1889.	Recovered.	Large soft "cauliflower" mass protruding through widely dilated os on admission. This was removed immediately and vaginal hysterectomy performed on a subsequent occasion.	42	Seen and examined Oct. 5th, 1893—i.e., nearly four years after operation—when there was no recurrence. Not seen since.
4	Cancer of cervix.	Oct. 23rd, 1890.	Recovered.	Definite "cauliflower" growth on posterior lip of cervix. Hæmaturia soon after the operation, lasting five days. Blood casts present. Pressure forceps used to broad ligaments. Clinical signs and symptoms seemed conclusive as to malignancy, but the microscopical examination not so.	41	This patient has been regularly seen up to and including the present year 1900. There has been no sign of recurrence.
5	Cancer of body.	March 17th, 1892.	Recovered.	Soft papillary growth projecting in cavity of body of uterus.	44	Free from recurrence for more than two and a half years after operation. Case fully recorded in the Transactions of the Obstetrical Society of London, vol. xxxvi., p. 374. Recurrence during the third year.
6	Cancer of cervix.	June 16th, 1892.	Recovered.	Little of the growth to be seen at the os uteri. The whole of the cervical canal up to the internal os was affected by the malignant growth. The cervix, in fact, converted into a thin shell lined with the growth.	59	Good health for two and a half years after operation, then recurrence took place in the scar. Recurrence during the third year.
7	Cancer of body.	Feb. 1st, 1893.	Recovered.	An example of "hard" cancer of the body of the uterus—the rarer variety.	53	Still quite well—more than seven years since the operation.
8	Cancer of body.	June 8th, 1893.	Recovered.	An example of "hard" cancer of the body of the uterus.	57	Still remains quite well. Last examined at the London Hospital July 19th, 1900. No sign of recurrence.
9	Cancer of cervix.	July 20th, 1893.	Recovered.	—	35	Recurrence during the second year.
10	Cancer of cervix.	August 4th, 1893.	Recovered.	—	38	Died. Recurrence during the second year.
11	Cancer of body.	August 21st, 1893.	Recovered.	Soft papillary growth. Perineum had to be incised. After one side of uterus freed it was brought into the vagina by forceps like small midwifery forceps.	54	Came up to the hospital and was examined November, 1893, three months after operation. Quite well and no sign of recurrence. All efforts to trace her since failed as she had left the former address.
12	Cancer of cervix.	August 28th, 1893.	Recovered.	Soft mushroom-like growth affecting both lips. I thought at the time of operation that the left broad ligament and left utero-sacral ligament were somewhat infiltrated and that probably, therefore, removal of the uterus had not removed all the diseased tissue.	42	She was seen and examined on Nov. 30th, 1893, when there was distinct evidence of recurrence in the top of the vagina. I think most probably that the whole of the cancerous tissue had not been removed by the hysterectomy. Recurrence during the first year.
13	Cancer of cervix.	Feb. 1st, 1894.	Died.	Deep laceration of cervix left side. Fatal amount of blood lost at operation.	48	—
14	Cancer of cervix.	Feb. 22nd, 1894.	Recovered.	A case of large "cauliflower" growth.	52	Recurrence took place in August, 1894. Recurrence during the first year.
15	Cancer of cervix.	Feb. 27th, 1894.	Recovered.	An extensive "cauliflower" growth. It was not till the patient was under an anæsthetic that the operation seemed worth trying.	57	This patient remained free from any sign of recurrence till she died in February, 1900. Mr. Howse, Barking-road, E., saw her several times in her last illness. She died from phthisis.
16	Cancer of cervix.	August 13th, 1894.	Recovered.	"Cauliflower" growth of the cervix. Round nodule of the size of a cobnut in left broad ligament. As the uterus could be easily drawn down it seemed worth trying whether removal of the uterus and also of the nodule would be effectual.	43	I believe recurrence took place not very long after the operation, but I had not the opportunity of examining the patient after she left London. Recurrence during the first year.
17	Cancer of cervix.	August 16th, 1894.	Recovered.	An example of the nodular and infiltrating form of the disease, the whole cervix being much thickened by it. Little or no growth projecting from the vaginal portion.	32	Recurrence during the first year.
18	Cancer of cervix.	August 30th, 1894.	Died on seventh day from peritonitis.	A large "cauliflower" growth. Patient doing well till pressure forceps were removed at the end of the second day, when she complained of pain, and within a few hours symptoms of peritonitis appeared. In removing forceps the general cavity of the peritoneum must have been reopened. Since this case I leave on forceps at least three days.	39	—

TABLE I.—40 CONSECUTIVE CASES OF VAGINAL HYSTERECTOMY PERFORMED FOR CANCER OF THE UTERUS—(*Continued*).

Case.	Disease.	Date of operation.	Immediate result.	Remarks.	Years of age.	Remote result.
19	Cancer of cervix.	Oct. 13th, 1894.	Recovered.	Cancer involving the substance of the cervix; little projecting growth. Patient had been told at another hospital that the case was too far advanced for operation.	52	Has been seen at frequent intervals at London Hospital since operation and has remained quite well; last examined March 15th, 1900.
20	Cancer of cervix.	December, 1894.	Recovered.	The removal of the uterus probably did not remove all the tissue infiltrated by the malignant growth.	45	Recurrence during the first year.
21	Cancer of cervix.	Feb. 14th, 1895.	Recovered.	Large "cauliflower" growth.	26	Recurrence during the first year.
22	Cancer of cervix.	April 25th, 1895.	Recovered.	Large "cauliflower" growth especially affecting the posterior lip of cervix. Was doubtful at time of operation if all infiltrated tissue was removed.	35	Seen and examined on several occasions, the last time on June 16th, 1898, when the scar was quite healthy. Heard that she went to America and died either at the end of 1898 or early in 1899; no information as to cause. As there was no sign of recurrence on June 16th, 1898, it seems at least equally likely that she may have died from some independent cause.
23	Cancer of cervix.	June 1st, 1895.	Recovered.	Large "cauliflower" growth, the part of the growth in the cervical canal just reaching internal os. There was a very large pyometra, the pus being horribly offensive.	55	She has remained well since the operation. She has gone to Australia, but writes to me on each anniversary of her operation. The last letter, dated June 11th, 1900—five years after the operation—says she was then quite well.
24	Cancer of body.	August 30th, 1895.	Recovered.	A large papillary growth projected into the cavity of the endometrium.	48	Well May 18th, 1897: also heard from her in May, 1900, that she was quite well.
25	Primary tuberculous ulceration of cervix.	Jan. 30th, 1896.	Recovered.	At time of operation growth was believed to be cancer of cervix.	36	Quite well in November, 1899.
26	Cancer of cervix.	April 16th, 1896.	Recovered.	Large "cauliflower" growths of cervix.	35	Examined Jan. 11th, 1899; a granular mass, size of raisin, at upper part of vagina. Seen recently, mass just the same, and evidently not malignant. Quite well March 15th, 1900.
27	Cancer of cervix.	Sept. 7th, 1896.	Recovered.	Nodule of malignant growth; size cob-nut or thereabouts, posterior lip. Anterior lip appeared quite healthy. Supra-vaginal amputation done first, then on slitting up cervix the growth found to extend up to internal os, so body of uterus was then also removed.	45	Well up till three years after operation. Then came to London hospital in February, 1900, with moveable mass size of fœtal head in hypogastric region. Evident recurrence in scar and under vaginal walls. The glands in right groin enlarged. Cachectic; no projection growth in region of scar, and only slight bleeding on examination. Recurrence during the fourth year.
28	Cancer of body.	Nov. 12th, 1896.	Recovered.	Secondary hæmorrhage in third week after operation requiring application of Wells's forceps. Ureteral fistula persisting for some three or four months, then healed spontaneously.	49	Recurrence in the recto-vaginal septum during the first half of 1900. Recurrence during the fourth year.
29	Sarcoma of body.	Feb. 11th, 1897.	Recovered.	See Transactions of the Obstetrical Society of London for full report of case.	24	Quite well March 24th, 1900.
30	Cancer of cervix.	June, 1897.	Recovered.	—	About 60	Recurrence took place about a year after the operation. Recurrence during the first year.
31	Cancer of cervix.	August, 1897.	Recovered.	—	60	Recurrence took place and she died May 19th, 1898. Recurrence during the first year.
32	Cancer of body.	Sept. 4th, 1897.	Recovered.	There were some mucous polypi attached to the lower part of cervix. The malignant growth was in the body.	61	Last examined July 7th, 1900. No sign of recurrence.
33	Cancer of cervix.	Sept. 6th, 1897.	Recovered.	—	38	Well June 21st, 1900.
34	Cancer of cervix.	Sept. 23rd, 1897.	Died three weeks after the operation from pneumonia.	The only case I have had in which cancer of the cervix affected a procident uterus. This patient was mentally feeble and very difficult to manage after the operation. At the post-mortem examination the pneumonia was said to be not septic and the parts in the neighbourhood of Douglas's pouch were looking healthy.	53	—
35	Cancer of cervix.	Oct. 5th, 1897.	Recovered.	A rather advanced case.	52	Died from recurrence July, 1898, the scar remaining unaffected to the last. Recurrence during the first year.
36	Cancer of cervix.	Dec. 2nd, 1897.	Recovered.	—	46	Examined and found quite well March 22nd, 1900, more than two years since the operation.
37	Cancer of cervix.	May 12th, 1898.	Recovered.	A rather advanced case, with large conical ulcer.	38	Recurrence took place March, 1899. She became much worse June 5th, 1899, and died soon after. Recurrence during the first year.

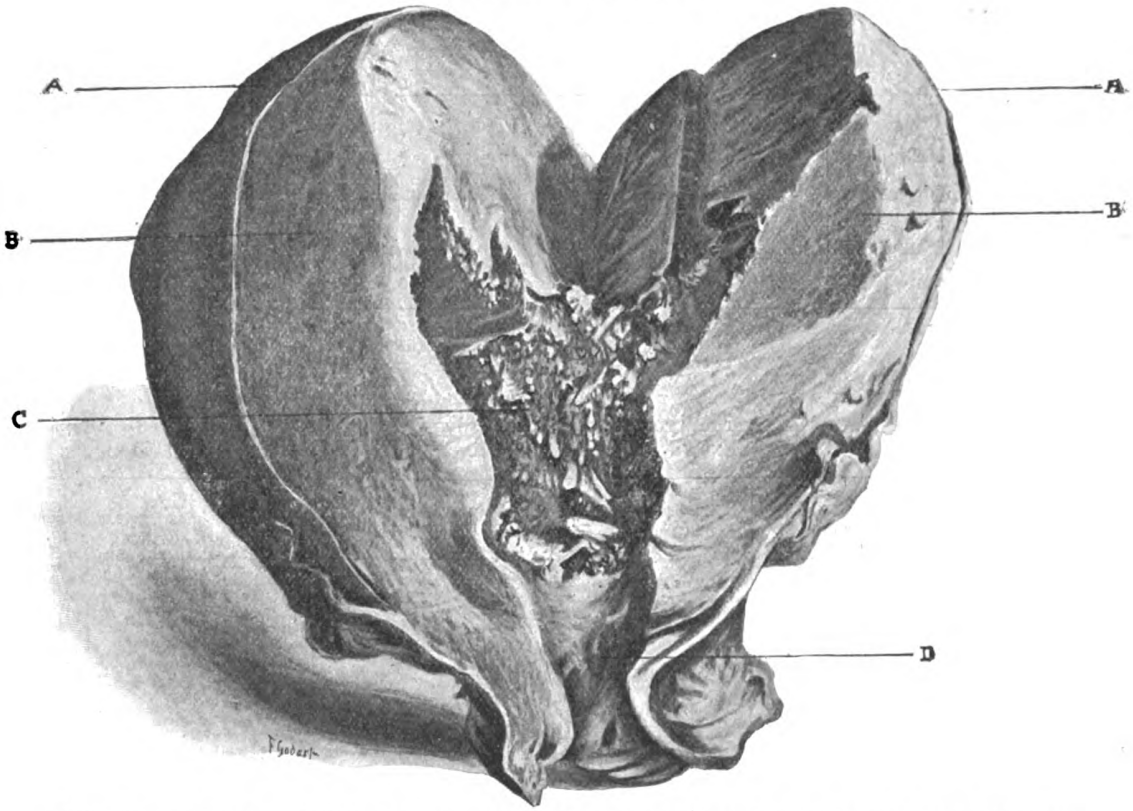
Case.	Disease.	Date of operation.	Immediate result.	Remarks.	Years of age.	Remote result.
38	Cancer of body.	May 14th, 1898.	Recovered.	—	About 50	—
39	Cancer of cervix.	Feb. 16th, 1899.	Recovered.	Bleeding on taking off forceps, requiring application of one pair more for another two days.	36	Quite well July 26th, 1900.
40	Cancer of cervix.	April 27th, 1899.	Recovered.	The disease affected both the vaginal and supra-vaginal portions of the cervix.	36	Recurrence early in 1900. Recurrence during first year.

TABLE II.—12 CASES OF VAGINAL HYSTERECTOMY FOR CANCER OF THE UTERUS IN WHICH THE DISEASE IS KNOWN NOT TO HAVE RECURRED.

Case.	No. of case in Table I.	Disease.	Date of operation.	Place of operation.	Interval since operation without recurrence.	Microscopical characters of growth.
1	7	Cancer of body.	Feb. 1st, 1893.	Private; with Mr. Stott, of High-gate-road, and Dr. C. Godson.	Seven years and four months. I saw her on June 18th, 1900.	Extract from Clinical Research Association's Report (Mr. Targett): "The growth may be described as a villous carcinoma."
2	8	Cancer of body.	June 8th, 1893.	London Hospital; sent to me by Mr. Best of Dover.	Seven years. Examined July 19th, 1900, at the London Hospital. No recurrence.	Extract from Clinical Research Association's Report (Mr. Targett): "A soft columnar-celled carcinoma."
3	15	Cancer of cervix, large "cauli-flower."	Feb. 27th, 1894.	Private; with Mr. Howse, then of Barking-road, E., now of Reading.	Six years.	Extract from Clinical Research Association's Report (Mr. Targett): "The nature of the growth is undoubtedly squamous-celled epithelioma."
4	19	Cancer of cervix.	Oct. 13th, 1894.	London Hospital. Sent to me by Mr Howse of Reading.	Five and a half years (up to March 15th, 1900, when the patient was last examined).	Extract from Clinical Research Association's Report (Mr. Targett): "The substance of the cervix is infiltrated with branching processes of squamous-celled epithelioma."
5	23	Cancer of cervix; large "cauli-flower" Pyometra.	June 1st, 1895.	Private; sent to me by Mr. Garry Simpson of Acton.	Five years. Heard from her in letter dated June 11th, 1900, that she was quite well.	Extract from Clinical Research Association's Report (Mr. Targett): "Solid branching columns of squamous-celled epithelioma are shown infiltrating the substance of the cervix uteri."
6	24	Cancer of body.	August 30th, 1895.	London Hospital.	Four and three-quarter years (up to May, 1900, when I heard from her that she was quite well).	Extract from Clinical Research Association's Report (Mr. Targett): "The growth from the body of the uterus is a soft, glandular-celled carcinoma, which has extensively infiltrated the muscular substance."
7	26	Cancer of cervix.	April 16th, 1896.	London Hospital; sent to me by Dr. Dunlop of Purfleet.	Nearly four years. I saw her on March 15th, 1900, and she was quite well.	Extract from Clinical Research Association's Report (Mr. Targett): "This portion of the cervix uteri is thickly infiltrated with a soft squamous-celled epithelioma."
8	29	Sarcoma of body, "deciduoma malignum."	Feb. 11th, 1897.	London Hospital.	More than three years (up to March 24th, 1900, when I last examined her).	For full report of this case see the Transactions of the Obstetrical Society of London, vol. xxxix., for 1897, p. 246.
9	32	Carcinoma of body.	Sept. 4th, 1897.	Private; with Dr. Pope of Kington, Hereford.	Two years and 10 months (up to July 7th, 1900, when I last examined her).	Extract from Clinical Research Association's Report (Mr. Targett): "The tissue from the body of the uterus is extensively infiltrated with a soft columnar-celled carcinoma."
10	33	Cancer of cervix.	Sept. 6th, 1897.	London Hospital.	Two years and nine months (up to June 21st, 1900, when I last examined her).	Extract from Clinical Research Association's Report (Mr. Targett): "The substance of the cervix uteri is extensively invaded with thick branching processes of squamous-celled epithelioma."
11	36	Cancer of cervix.	Dec. 2nd, 1897.	London Hospital.	Two years and nearly four months (up to March 22nd, 1900, when I last saw her).	Extract from Clinical Research Association's Report (Mr. Targett): "The growth in the cervix uteri is a malignant adenoma—that is, a columnar-celled carcinoma in which the cells preserve their tubular arrangement."
12	39	Cancer of cervix.	Feb. 16th, 1899.	London Hospital.	One year and five months (up to July 26th, 1900, when I last examined her).	Extract from Clinical Research Association's Report (Mr. Targett): "The cervix is very extensively invaded with squamous-celled epithelioma. Some of the epithelial processes are large and the central cells have undergone granular degeneration. In others there are small cell-nests."

FIG. 1 (CASE 8, TABLE I.).



Vaginal hysterectomy, June 8th, 1893. The patient was seen and examined at the London Hospital on July 19th, 1900, and found to have no sign of recurrence. A, Peritoneum. B, Cut surface of uterine wall. C, Growth in endometrium, "a soft columnar-celled carcinoma." D, Cervical canal.

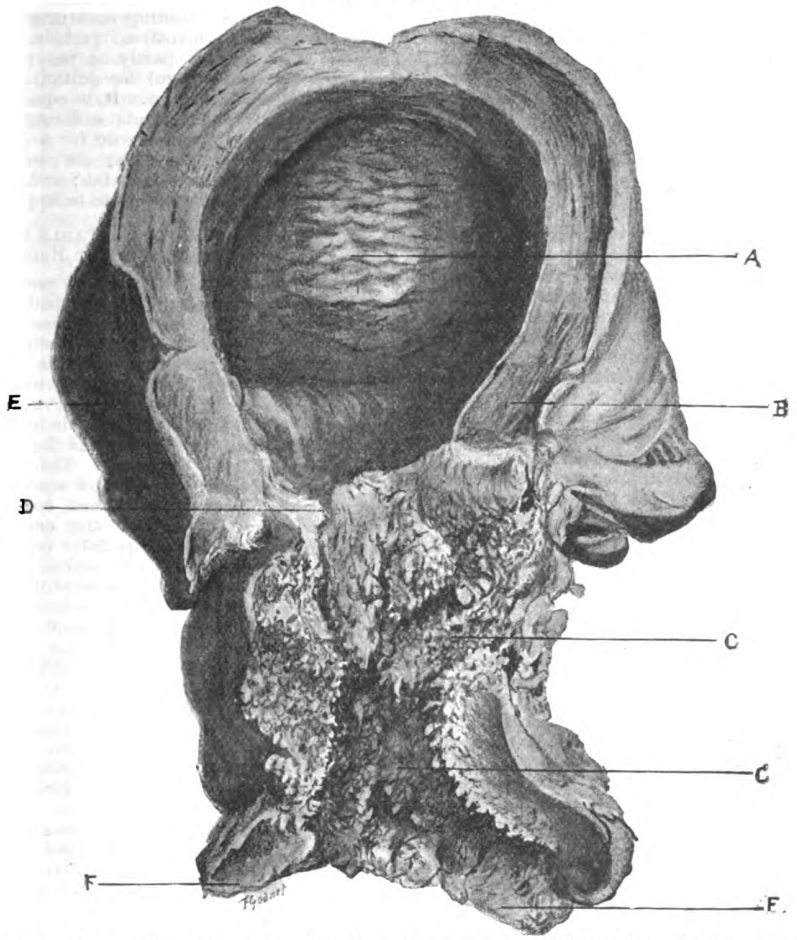
FIG. 2 (CASE 8, TABLE I.).

High power. In this figure the columnar character of the cells is shown, and although the tubules and alveoli everywhere exhibit a central cavity or lumen, yet there are abundant signs of epithelial proliferation, and the cells encroach on the central space. In the well-marked tubular structure of the growth this specimen resembles the so-called malignant adenoma. (Mr. Targett's description.)

FIG. 3 (CASE 8, TABLE I.).

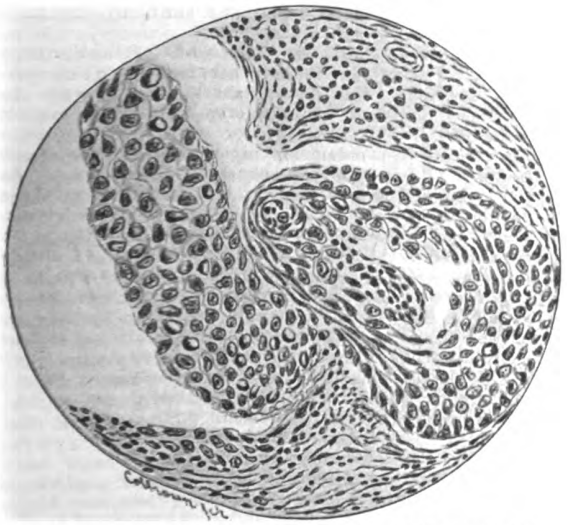
Low power. The figure represents a portion of uterine wall composed of interlacing bundles of muscular tissue and extensively invaded by a soft columnar-celled carcinoma. The cells are arranged in tubules and elongated spaces which have a definite lumen, and the stroma consisting of uterine muscle is very scanty. (Mr. Targett's description.)

FIG. 4 (CASE 23, TABLE I.).



Vaginal hysterectomy, June 1st, 1895. I heard from the patient (who is in Australia) in a letter dated June 11th, 1900, that she is quite well. A, Cavity of the body of the uterus enormously dilated; it contained fœtid pus (pyometra), which escaped during the operation. B, Cut surface of the wall of the body of the uterus. C, Growth in the cervix, "squamous-celled epithelioma." D, Internal os. E, Peritoneal surface of the uterus. F, External os.

FIG. 5 (CASE 23 TABLE I.).



High power. The squamous character of the epithelial cells is here represented, and in the centre keratoid and other degenerative changes have taken place. The cells have separated from the stroma by shrinkage. (Mr. Targett's description.)

FIG. 6 (CASE 23, TABLE I.).

Low power. Solid branching columns of squamous-celled epithelioma are shown infiltrating the substance of the cervix uteri. Large cell-nests are present as well as areas of granular degeneration in the centres of the epithelial processes. (Mr. Targett's description.)

malignant disease. It will be seen that there were no recurrences later than during the fourth year after operation, so that when a patient has passed through four complete years without recurrence there seems to be some probability that she may remain perfectly well.

[Dr. Lewers here referred to the mortality of the operation and discussed some points in the technique. He believed it to be a good plan when operating for cancer of the cervix, after the cervix has been freed, to apply Paquelin's cautery to the cut surfaces adjacent to the growth. He then discussed some complications of vaginal hysterectomy—secondary hæmorrhage and injuries of the bladder and ureters.]

CASES SUITABLE FOR VAGINAL HYSTERECTOMY.

When there is evidence that the disease has spread beyond the anatomical limit of the uterus in any direction it is, I believe, hopeless to expect any permanent benefit from vaginal hysterectomy, even if it is possible to perform the operation. In many cases it is at once evident on examination that the growth has spread far beyond the uterus. No difficulty arises in coming to a conclusion in such cases. In other cases where on an ordinary examination the mobility of the uterus appears to be unimpaired it is not so easy to decide. The uterus may be freely moveable, yet the base of the bladder may be involved. Again, the mobility at an ordinary examination may seem normal, yet when an attempt is made to draw the cervix down to the vulva a check is felt at one side or the other in the region of the broad ligaments or of the utero-sacral ligaments due to the extension of the malignant growth in the corresponding direction. This extension can generally be best appreciated by examining per rectum while the cervix is being drawn down with a volsella. Cases of this kind are certainly unsuitable for radical operation. It may be possible to remove the uterus, but that is of little use if a portion of broad ligament or utero-sacral ligament infiltrated with the malignant growth is left behind. In most of these doubtful cases the best plan is to make a careful examination under anæsthesia before deciding as to operation. For my own part, I have never felt it to be justifiable to perform an operation like vaginal hysterectomy as a palliative operation—in other words, to perform it where one feels certain that the patient has not even a chance of obtaining any permanent benefit. On the other hand, there may be a very extensive growth and yet, if it does not seem to have extended beyond the uterus, operation is advisable. One must not be too ready to reject cases as hopeless. Case 22 in this series is a good example of this. The growth from the cervix was a very large one of the "cauliflower" type and yet the patient certainly remained well for more than three years after the removal of the uterus. I am not even certain that she had recurrence, as, though she is dead, she died in America a comparatively short time after I last examined her and there was then no sign of recurrence. Again, in Case 19 the patient had been told at another hospital that her case was too advanced for operation, yet she remains well more than five years after the operation. In Case 15 also, though the growth is obviously a large one, the patient remained free from recurrence for six years, when she died from phthisis. Case 23 is another instance in point; the growth is a large one, but the patient remains well five years after operation. These cases, then (Cases 15, 22, and 23), go to show that the size of the growth from the cervix is relatively of small importance and that the essential point is whether there is any extension to the tissues outside the uterus itself.

Table I. is a list of the 40 vaginal hysterectomies for cancer which I had performed up to April, 1899, with some of the more important details of the cases. Table II. is a list of the 12 cases in which the disease is known not to have recurred.

CONCLUSIONS FROM THE TABLES.

The conclusions that appear to follow from a consideration of the facts in this paper are: (1) that in a certain proportion of cases patients suffering from cancer of the uterus may be relieved by operation for periods of many years—in some cases for so long a time, seven years and upwards, that there seems some probability that the relief may be permanent; (2) that the proportion of cases in which this result can be expected must remain very small so long as patients generally only seek advice at a late stage of the disease; and (3) that consequently the great desideratum is early diagnosis. Improvement in this direction depends to some extent on a better appreciation on the part of women themselves of the early symptoms of the disease, and especially of the significance of bleeding after the menopause, or of bleeding occurring at an earlier time of life between the menstrual periods. Early diagnosis, of course, also depends partly on the profession. Especially important is the general recognition of the gravity of the symptom just mentioned. It is equally important also to bear in mind that patients suffering from cancer of the uterus may, and generally do for a relatively long period, look quite well. They may be well nourished, or not infrequently even excessively fat; and, as regards the aspect of the face, they may appear to be in perfect health.

NOTES OF THE 12 CASES (TABLE II.) IN WHICH THE DISEASE HAS NOT RECURRED.

CASE 7.—The patient was 53 years of age. She had been married 21 years; she had had no children, but two miscarriages, each at about three months, the last 13 years before I saw her. I was asked to see her in consultation with Dr. Clement Godson and Mr. T. S. Stott of Highgate-road. The symptoms were continued hæmorrhage for seven or eight months, with occasional profuse losses of blood and severe pain in the hypogastric region. On examination the uterus was found to be moderately enlarged and freely moveable. The vaginal portion of the cervix was normal. The sound occasioned very free bleeding. It was agreed that the best course would be to dilate the cervix and to examine the endometrium. This was accordingly done. Two specially prepared laminaria tents were inserted, and on the next afternoon the dilatation of the cervix was completed with Hegar's dilators under anæsthesia. There was a hard, irregular condition of the inside of the body of the uterus. Nothing could be detached either with the finger or with a curette. The diagnosis rested on the symptoms, and on the fact that the condition of the endometrium could not be classified as belonging to any non-malignant state. I advised that vaginal hysterectomy should be performed, and I carried out the operation on Feb. 1st, 1893, assisted by Dr. Godson, Mr. Stott, and Dr. J. H. Sequeira, the last of whom was resident accoucheur at the London Hospital at that time. Mr. F. W. Braine gave the anæsthetic. The patient made a good recovery.

A section from the uterus was made by the Clinical Research Association and reported on by Mr. Targett as follows: "The growth of the uterus is a columnar-celled carcinoma of the body of the villous type. It has deeply invaded the muscular substance."

The patient came to see me on June 8th, 1900, to show me that she was quite well. The interval in this case without recurrence is, therefore, seven years and four months. Her present medical attendant is Dr. Andrew Brown of Lancaster-road, Belsize-park.

CASE 8 (see Figs. 1, 2, and 3).—A married woman, aged 57 years, was admitted under my care into the London Hospital on May 1st, 1893. She was sent up to me by Mr. W. G. Best of Dover.

Previous history.—She was born at Blackburn in Lancashire. During her infancy her family removed to Crayford, in Kent. Her circumstances had always been comfortable. She had scarlet fever in childhood and cholera in 1849.

Menstruation.—The catamenia began when the patient was between 14 and 15 years of age. There was some irregularity for the first 10 months, but after that she was very regular every four weeks, and did not lose very much. She always suffered a great deal of pain after the periods. She was married at the age of 33 years and had six children, but no miscarriages. The last confinement was 14 years ago.

Present illness.—About two years ago the periods began to be irregular. She would "see nothing" for two or three months, and then a period would come on with an excessive loss, containing clots. During the last 18 months she had been losing blood constantly, and for the same time had suffered a good deal of pain, more severe at night, in the lower part of the abdomen. She was closely questioned as to the time when the various symptoms arose, and it became clear that as long ago as two years there was a red discharge between the periods, and that for the greater part of the last two years she had had a good deal of pain in the back and lower part of the hips. She said, also, that she always had suffered a great deal of pain during her periods from the time they began. As she grew older the pain at the periods was not so severe until

about two years ago, when it re-commenced. The pain during these two years had been constantly present, and had increased in severity. Her state on May 1st, 1893, was as follows. She was a stout, heavy woman and as regards the appearance of the face she did not look very ill. There was no cachexia. Her weight on admission was 12 st. 13½ lb. Nothing abnormal could be felt on examination of the abdomen. On vaginal examination there was a considerable descent of the anterior vaginal wall, which protruded from the vulva. There was an extensive rupture of the perineum, reaching back to the edge of the sphincter. There was also slight prolapse of the rectal mucous membrane. Through the speculum the vaginal portion of the cervix appeared to be healthy. The uterus was fairly moveable and in the normal position. The body of it was somewhat enlarged and the sound passed three and a quarter inches, causing rather free bleeding. She was kept under observation in the hospital during the whole of May, and during that time there was a constant red vaginal discharge, and she complained of pain about the lower part of the abdomen, more severe at night. On May 31st, at 5 P.M., two specially prepared laminaria tents were inserted into the uterus with strict antiseptic precautions, and on the following day (June 1st), at 2 P.M., she was anæsthetised with ether. The tents were removed, and it was found that the cervix admitted the index finger easily. The uterus was drawn down to the outlet with a volsella. The finger when passed into the uterus detected a hard, irregular condition of the endometrium; this was particularly marked at the upper part and to the right. I could not classify the condition as resembling any non-malignant pathological state, and I came to the conclusion that the case was one of primary carcinoma of the body of the uterus. I should have mentioned that nothing could be scraped away from the endometrium with a curette.

Operation.—On June 8th, 1893, the patient was anæsthetised with ether and placed in the lithotomy position. The vulva and vagina were thoroughly disinfected with percbloride lotion 1 in 1000. Having drawn down the cervix the anterior fornix was incised first and the bladder was separated from the cervix as high as the internal os. The posterior fornix was then similarly incised, and Douglas's pouch was opened. The cervix was cleared laterally as high as the level of the internal os, pressure forceps being used to control the bleeding where necessary. The utero-vesical pouch of the peritoneum was then opened. The remaining lateral attachments were clamped piece by piece, the left broad ligament being first secured and divided. The uterus was then, as it were, delivered, the left side of it first, so that at this stage it was hanging by the right broad ligament. The latter was then secured with pressure forceps and divided. The uterus was then removed. The vagina was filled with iodoform gauze, the upper part of the plug projecting for an inch or so into Douglas's pouch. The patient's progress after the operation was very satisfactory. The highest temperature in the first week was 100·8° F. on the evening of June 11th. On one occasion in the second week (June 16th) it reached 101·4°. After June 20th the temperature was practically normal, only once after that date reaching 100°. The pressure forceps were removed on the afternoon of June 10th. The patient went home on July 21st, 1893. I have seen her every summer since the operation and have examined her. The last time the patient was examined was on July 19th, 1900, at the London Hospital. So far she has remained free from any sign of recurrence and appears to be in perfect health.

Sections for examination under the microscope were prepared by the Clinical Research Association, and reported on by Mr. Targett as follows: "This growth from the body of the uterus is a columnar-celled carcinoma, in which the tubular arrangement of the cells is well preserved. The tissues have shrunk in hardening, but the sections are sufficiently good for microscopic drawings."

CASE 15.—A married woman, aged 57 years, was seen by me in consultation with Mr. P. W. M. Howse, then of Barking-road, E., but now of Reading, in February, 1894. She had had 13 children, the last 15 years ago, and two miscarriages some time before the last confinement. The complaint when I saw her was that she had been losing blood from the vagina for the last eight weeks. Before this appeared there had been a yellow vaginal discharge for nine months. She had had no pain. She thought that she had lost flesh and said that her appetite was bad. The menopause occurred at 51 years of age. On examination there was found a large "cauliflower"-like growth springing from the vaginal portion of the cervix, forming a ring of soft projecting growth round the os uteri, and bleeding readily on examination.

It was decided to make a thorough examination under anæsthesia, with the understanding that if the conditions were found favourable the uterus should be removed. Accordingly, on Feb. 27th, 1894, the patient was anæsthetised. It was then found that the uterus could be drawn easily down to the vulva and that the growth did not seem to have spread beyond the limits of the cervix. There was a ring of apparently healthy vaginal portion outside the malignant growth all the way round it. This can be well seen even now in the specimen. The uterus was accordingly removed, the steps of the operation being much the same as in the preceding case, except that Paquelin's cautery was very freely applied to the cut edges of the vaginal fornices and neighbouring tissue from which the cervix had been detached. The patient made a very good recovery. I heard of her from time to time from Mr. Howse. She remained free from recurrence. Mr. Howse saw her several times in the course of her last illness (phthisis) and there was no return of the cancer up to the time of her death, which occurred in February, 1900, and was due to phthisis. Mr. Howse had attended her many times in former years for lung trouble. The interval since the operation without recurrence is, therefore, in this case six years.

Sections of the growth for the microscope were prepared by the Clinical Research Association and reported on by Mr. Targett as follows: "The second portion of this growth has been examined, but the tissue is so necrotic that the sections are not worth drawing. The nature of the growth is undoubtedly squamous-celled epithelioma, but owing to decomposition the cells are much vacuolated and the tissue has, therefore, an unnatural spongy appearance. It is not worth the expense of a drawing." I may add that the uterus had been more than five years in spirit before Mr. Targett had a piece of the growth for sections.

CASE 19.—The patient, a married woman, 52 years old, was admitted under my care into the London Hospital on Oct. 9th, 1894. She had had two children, the last one 26 years ago, but had never had any miscarriages. For the last eight years she had been a monthly nurse. She had always enjoyed good health and there was no history of any previous illness. She had always had a comfortable home. She had been a teetotaler all her life and had always lived in or near the East-end of London. Her two children were born within three and a half years of her marriage.

Menstrual history.—The catamenia appeared when she was 13 years old and she was always regular every four weeks except when she was pregnant. She always suffered very much from headache at the menstrual periods. The menopause occurred five years previously—i.e., in 1889. After the menopause she "saw nothing" till the end of June, 1894, when on awaking one morning she found that she had lost a considerable quantity of blood during the night. Throughout the whole of July, 1894, she continued to have a series of losses which occurred irregularly, the discharge being blood-stained and offensive. Occasionally it ceased altogether for two or three days. In August there was much less discharge, but since then it had continued more or less. She had been able to continue at her work. She consulted Mr. Howse in September, 1894, and afterwards was an in-patient at the Samaritan Hospital for four days. She said that she was told there that the disease was too far advanced for any operation to be advisable.

A month before her admission to the London Hospital—i.e., October, 1894—she first noticed a pain in the left iliac and in the hypogastric regions. It was of a burning character, not relieved by lying down, and not worse at night. The pain had gradually become more severe. A week before her admission she began to feel a pricking and shooting sensation in the left breast. She said that she had not been getting thinner.

On admission she was fairly well nourished but rather sallow. On Oct. 11th (1894) she was examined under anæsthesia. On vaginal examination there was no obvious projecting growth, the only suggestive point on gentle examination being that the external os was unusually patulous. On pressing the finger firmly into the os a soft friable growth could be felt occupying the cervical canal. The uterus was drawn down to the vulva with a volsella and came down easily. The vaginal fornices seemed to be free from any infiltration. On examining bimanually no

extension of the disease into the broad or utero-sacral ligaments could be made out.

Operation.—On Oct. 13th, 1894, the patient was anæsthetised with ether and placed in the lithotomy position. Vaginal hysterectomy was then performed. Wells's forceps were used for securing the vessels. The vagina was packed with iodoform gauze and the upper part of the gauze plug was pushed into the pouch of Douglas. The gauze and forceps were removed 96 hours after the operation, but no vaginal douches were given till the 24th, when she was ordered vaginal douches of weak iodine water twice daily. The temperature after the operation did not rise above 100·4° F. and the patient made an uninterrupted recovery.

Examination of the uterus after removal.—The body of the uterus was not appreciably enlarged, and, so far as could be judged by the naked eye, the disease had not extended into it. An interesting point, however, was that at one part of the fundus there was a white nodule of circular shape of the size of a pea in the thickness of the uterine wall. Microscopical examination of this nodule subsequently showed that it was a small fibro-myoma.

Sections of the cervix were prepared by the Clinical Research Association and were reported on by Mr. Targett as follows: "The substance of the cervix uteri is infiltrated with branching processes of squamous-celled epithelioma. There are a few cell-nests and some of the larger processes show granular degeneration of the central cells. The section is suitable for drawing."

I saw this patient last on March 15th, 1900, at the London Hospital, and examined her. The scar was quite healthy and she was herself perfectly well. The interval since the operation in this case is, therefore, five and a half years.

CASE 23 (see Figs. 4, 5, and 6).—The patient, who was 55 years of age, was brought to see me by Mr. Garry Simpson of East Acton on May 17th, 1895. She had had six children, the last 17 years previously, and two miscarriages, both before the date of the last confinement. The menopause occurred at the age of 50 years. Since then she had "seen nothing" till August, 1894. Since that time there had been a constant red discharge from the vagina and for the last two or three weeks the discharge had been offensive. She felt ill and worn out at the time when the vaginal discharge commenced. For some time she had suffered from continuous pain in the lower abdomen; the date of its commencement could not be fixed. Of late she had been getting rapidly thinner. On examination of the abdomen nothing abnormal could be felt. On vaginal examination a large "cauliflower" growth was felt springing from the vaginal portion of the cervix. The uterus seemed freely moveable and the body of the uterus seemed considerably larger than normal in a woman past the menopause. She went into Fitzroy House for the purpose of having the uterus removed and during the time—a few days—she was there before the operation the temperature at night was 100° F. or thereabouts as a rule.

Operation (June 1st, 1895).—Vaginal hysterectomy was performed in a manner similar to that already described in the preceding cases. At one stage of the operation the whole field became suddenly inundated with horribly fœtid pus. This came from the body of the uterus and had been let out by a laceration about the junction of the cervix and body caused by traction with the volsella. The pus had previously been pent up in the body of the uterus by occlusion of the os internum, constituting the condition known as "pyometra." In spite of the fact that the whole region of the wound was fouled with this fœtid pus the convalescence was quite uninterrupted.

A portion of the cervix was sent to the Clinical Research Association for microscopical examination and Mr. Targett reported on it as follows: "The growth from the cervix uteri is a squamous-celled epithelioma of the papillary type. There is a considerable amount of keratoid change in the epithelial processes."

A drawing of the uterus and two drawings of the section accompany this paper.

This patient writes to me every year on the anniversary of her operation. As she is now living in Australia I do not actually get the letter for some weeks afterwards. I have had a letter from her this year (1900) dated June 11th, and in it she says that she still continues quite well. The uterus shows well the enormous distension of the cavity of the body by the pus referred to above and it also shows an extensive cauliflower-like growth from the cervix extending up the cervical canal to the internal os.

CASE 24.—A married woman, aged 48 years, was admitted under my care into the London Hospital on August 21st, 1895, at the request of Dr. W. H. G. Aspland.

Previous history.—She had been married 21 years but had been a widow for 15 years. She had never been pregnant. The catamenia appeared when she was about 15 years old. She had dysmenorrhœa when she was single but suffered much less from this after her marriage. The menopause occurred about three years previously.

Present illness.—She had not been well for some time. For the last seven or eight months she had had a yellow vaginal discharge mixed with blood more often than not. She had no pain when the discharge began, but for the last two months she had pain in the left iliac region occasionally. It gradually became more severe and was also felt at times across the lower abdomen and in the lower part of the back. It was clear, however, that a blood-stained discharge and a feeling of not being in good health were for some months the only symptoms. She said on admission that she felt weaker than formerly but did not think that she had lost flesh. Her appetite latterly had not been good.

On admission nothing abnormal was detected on examination of the abdomen. On vaginal examination some blood-stained discharge was seen about the vaginal orifice and in the vagina. It was not offensive. The uterus was found to be strongly retroverted; the vaginal portion of the cervix was rather soft but otherwise normal. The uterus was easily replaced with the sound, which passed three and a quarter inches. On bimanual examination the uterus was found to be freely moveable and the body of it uniformly enlarged. On August 23rd two small laminaria tents were put into the cervix, and on the next day the dilatation of the cervix was completed under anæsthesia with Hegar's dilators up to No. 19. On passing the finger into the uterus a growth of about the size of a walnut was found projecting from the posterior wall. It had a papillary surface and was very friable, portions being easily broken off with the finger.

Operation.—Vaginal hysterectomy was performed on August 30th, 1895, the steps of the operation being similar to those adopted in the preceding cases. The pressure forceps and gauze were removed on the fourth day, and the patient made an uninterrupted recovery, leaving the hospital on Sept. 23rd.

A portion of the growth was sent to the Clinical Research Association for microscopical examination and Mr. Targett reported on it as follows: "The growth from the body of the uterus is a soft glandular-celled carcinoma which has extensively infiltrated the muscular substance. The growth is of the columnar-celled type, though the tubular arrangement of the cells is not recognisable in the section."

I had a letter from this patient in May, 1900, to say that she was still quite well. The interval since the operation is, therefore, nearly five years.

CASE 26.—A married woman, aged 35 years, was admitted into the London Hospital under my care on April 6th, 1896. She was sent to me by Dr. J. Dunlop of Purfleet. She had been married 16 years and had had eight children; the last was eight months old. She had had one miscarriage five years previously. Menstruation had always been natural.

History of the present illness.—She had found herself getting thinner lately and had had a bad appetite. About three months previously she consulted a medical man on account of a yellow vaginal discharge which she had had for some months. During the last two months the discharge had increased in quantity and had been sometimes blood-stained. She had sometimes felt a pain in the lower abdomen and back, but pain did not seem to have been a marked feature in her present illness. On April 10th she was examined under anæsthesia. On vaginal examination a "cauliflower like" growth was seen springing from the vaginal portion of the cervix. The cervix could be easily drawn down to the outlet of the vulva with a volsella, and there was a good margin of apparently healthy tissue round the growth. The body of the uterus was not enlarged. The case seemed a suitable one for radical operation.

Operation (April 16th, 1896).—The patient was anæsthetised with the A.C.E. mixture. Vaginal hysterectomy was then performed, the method adopted being similar to that described in the preceding cases. The cut margin of the vaginal wall round the cervix was thoroughly seared with Paquelin's cautery. The patient made an uneventful recovery and went home on May 23rd, 1896.

A portion of the growth was sent to the Clinical Research Association for microscopical examination and Mr. Targett

reported on it as follows: "This portion of the cervix uteri is thickly infiltrated with a soft squamous-celled epithelioma. There are no typical cell-nests but a considerable number of cell-inclusions." I have seen this patient several times since the operation; the last time I examined her was on Oct. 12th, 1899, when there was no evidence of recurrence. I have also seen her on March 15th, 1900, when she said that she was quite well, but I did not examine her on that occasion. The interval since the operation in this case is, therefore, nearly four years.

CASE 29.—This was the case of primary sarcoma of the body of the uterus which formed the subject of a communication read before the Obstetrical Society of London, and which was published in Vol. xxxix., p. 246, of the Transactions of the Society. I only refer to it here for the purpose of recording the patient's subsequent progress. I have seen her this year (March 24th, 1900), more than three years since the date of her operation, and she remains free from any sign of recurrence.

CASE 32.—The patient, aged 61 years, was sent to me by Dr. H. B. Pope of Kington, Herefordshire. She had been married many years and had had two children, the last 28 years previously. I saw her on August 19th, 1897. She gave a history that nine years previously she had a fall and that there had been more or less discharge, occasionally blood-stained, from the vagina since. For the last two months there had been a constant discharge of blood every day. About a week before I saw her she had had a flooding and was said to have lost about a pint of blood. The menopause was said not to have occurred. She had not been getting thinner. On August 20th she was examined under anæsthesia. There were several mucous polypi hanging from the cervix. The uterus was considerably enlarged and was freely moveable. As I did not think the mucous polypi could have accounted for the flooding mentioned above I dilated the cervix and found a growth in the endometrium, a portion of which was detached for examination and sent to the Clinical Research Association. Mr. Targett reported on it as follows: "The tissue from the body of the uterus is extensively infiltrated with a soft columnar-celled carcinoma. The tubular arrangement of the cells is generally well preserved, but in certain parts of the section the growth has undergone caseation." The patient was accordingly advised to have the uterus removed.

Operation (Sept. 4th, 1897).—Vaginal hysterectomy was performed as in the preceding cases; the patient made a good recovery. I examined her last on July 7th, 1900. She was quite well and there was no sign of recurrence. The interval since the operation is, therefore, two years and 10 months.

CASE 33.—A married woman, aged 38 years, was admitted under my care into the London Hospital on Sept. 4th, 1897. She had been married 19 years and had had six children, the last three years previously, and two miscarriages, the last nine years previously. The catamenia appeared when she was 16 years old. The periods lasted four days and were preceded by severe pain for three days, which was relieved on the appearance of the flow. She was never regular every four weeks till the last four years, but since the last confinement she had been fairly regular till recently.

Present illness.—This began nine weeks previously, when bleeding occurred and continued for nearly five weeks. After an interval of three or four days she had a flooding and the loss of blood continued for eight days. She had had no pain but had been getting thinner the last six weeks, and her appetite during that time had been poor.

On examination (Sept. 5th, 1897) there was seen some blood about the external genitals. There was slight prolapse of both vaginal walls. There was marked enlargement of the anterior lip of the cervix, which was three or four times as thick from before backwards as the posterior lip. The growth on the anterior lip was raised and in shape like a horseshoe with the convexity forwards. The growth bled easily on examination and the sound pressed against it readily penetrated its substance. The body of the uterus was of normal size and the uterus was freely moveable.

Operation (Sept. 6th, 1897).—Vaginal hysterectomy was performed as in the preceding cases. She made a good recovery and left the hospital on Oct. 1st, 1897. Sections of the growth were prepared by the Clinical Research Association and reported on by Mr. Targett as follows: "The substance of the cervix uteri is extensively invaded with thick branching processes of squamous-celled epithelioma."

I last examined this patient on June 21st, 1900, at the London Hospital. She was then quite well and there was no sign of recurrence. The interval since the operation without recurrence is, therefore, two years and nine months.

CASE 36.—A married woman, aged 46 years, was admitted into the London Hospital under my care on Nov. 27th, 1897. She was sent to me by Mr. A. O. Honnywill of Sutton, Surrey. She had been married 27 years and had had four children, the last 19 years previously. She had a flooding in the last week of August, 1897; the loss of blood continued for three weeks; there was then an interval of three weeks without any loss. The bleeding then began again, and since then she had been losing blood almost constantly. She thought that she had been getting stouter.

On examination it was found that the anterior lip was the seat of a growth about equal to half-a-crown in area. The growth was raised and had an overhanging margin. The whole anterior lip from before backwards measured one inch and three eighths, the posterior lip similarly only three-eighths of an inch. The sound pressed against the growth readily penetrated its substance. Two small hard nodules were felt under the mucous membrane, one to the right of and the other above the growth. The uterus was freely moveable and there was no evidence of extension of the disease to the broad ligaments or utero-sacral ligaments.

Operation (Dec. 2nd, 1897).—Vaginal hysterectomy was performed, the method adopted being the same as in the preceding cases. Paquelin's cautery was used to sear the cut edges of the vaginal walls. There was slight pyrexia for the first fortnight after the operation, the highest point reached being 101° F. on the evenings of Dec. 6th and 7th. After the 7th the temperature was normal. The patient did well and went home on the 29th.

A portion of the cervix was sent to the Clinical Research Association for examination and Mr. Targett reported on it as follows: "The growth in the cervix uteri is a malignant adenoma, that is, a columnar-celled carcinoma in which the cells preserve their tubular arrangement. The tissues are deeply invaded and there is much small-celled growth around the proliferating tubules." I last examined the patient on March 22nd, 1900, at the London Hospital. There was no sign of recurrence and she expressed herself as feeling quite well. The interval since the operation is therefore two years and nearly four months.

CASE 39.—The patient, a married woman, aged 36 years, was admitted under my care into the London Hospital on Feb. 4th, 1899. She had had eight children, the last 11 months prior to her admission. She had also had two miscarriages. Her chief symptom had been a red vaginal discharge which had been present for 15 months. At times the bleeding had been severe. She had also had pain in the left iliac region for 10 months. She was suckling at the time of her admission. On Feb. 9th, 1899, the following note was made: "On the vaginal portion of the cervix is a raised and slightly irregular crescentic growth. It involves chiefly the left side of the vaginal portion immediately adjacent to the external os and about two-thirds of the posterior lip. It has an overhanging margin. About the middle of the anterior lip a little nodule, the size of a shot, is felt under the mucous membrane, the surface of which over the nodule is healthy. There is another similar nodule to the left of the first. There are also two nodules to the right under the mucous membrane of a similar character. The sound pressed against the crescentic growth enters its substance to the depth of an inch. The uterus is freely moveable, retroverted, and its body not enlarged. There is no evidence that the growth has extended beyond the limits of the cervix."

Operation.—On Feb. 16th, 1899, vaginal hysterectomy was performed in the same way as in the preceding cases, Paquelin's cautery being used to sear the cut edges of the vaginal wall. The forceps were removed on the 20th. Slight bleeding occurred, so that the region of the wound was exposed with Sims's speculum. A pair of Wells's small pressure forceps was used to secure the bleeding point. This pair was left on for two days and then removed. No further bleeding occurred. The temperature only rose above 99·5°F. on two occasions; one was on the evening of the 20th and the other was on the evening of the 22nd, when the temperature was 100·2° and 100° respectively. The patient went home on March 15th.

A portion of the growth was sent to the Clinical Research Association for microscopical examination and Mr. Targett reported on it as follows: "The cervix is very extensively

invaded with squamous-celled epithelioma. Some of the epithelial processes are large, and the central cells have undergone granular degeneration. In others there are small cell-nests."

I examined this patient on July 26th, 1900, and found no sign of recurrence. The interval since the operation in this case is therefore one year and five months.

Harley-street, W.

A CASE OF DEFORMITY OF THE SKULL SIMULATING LEONTIASIS OSSEA, ASSOCIATED WITH A CONDITION OF SYRINGOMYELIA; NO PHYSICAL SIGNS OF SYRINGOMYELIA PRESENT.

BY JAMES S. COLLIER, M.D., M.R.C.P. LOND.,
PATHOLOGIST TO THE NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, QUEEN-SQUARE, W.C.

THE following case is of peculiar interest as it exemplifies (1) the presence of syringomyelia in the absence of all the usual signs of that condition, and (2) a close simulation both in signs and symptoms of leontiasis ossea by a thin, deformed skull and meningeal ossification. I am indebted to Sir William Gowers and to Mr. Victor Horsley for permission to publish the notes, and to Dr. F. E. Batten for the pathological report.

A man, aged 36 years, was admitted into the National Hospital for the Paralysed and Epileptic, under the care of Sir William Gowers and Mr. Horsley, on March 7th, 1899, complaining of paralysis of the right arm, of fits commencing in the right arm, and of gradually increasing deafness. He was the youngest of a family of 13 and there was no history of hereditary disease. When four years of age he fell from a window, a distance of 20 feet, upon his head. He was unconscious for some days and was ill for two years after the accident, and from the time of its occurrence his head was noticed slowly to become deformed. The deformity of the head, which I shall subsequently describe, was plainly visible in a photograph of the patient at the age of five years. In childhood he broke each femur on separate occasions, and since the right femur was broken he had always walked with a limp. He learned the trade of a carpenter and earned a good wage for many years. At the age of 26 years he began to suffer with occasional fits, commencing in the right hand and these occurred at long intervals till the time of his admission into the hospital. Ten years before admission progressive deafness came on, and six years before admission his right shoulder became stiff and later the elbow and wrist became similarly affected and the muscles of the right arm wasted. After three years the right arm had become so useless as to necessitate his giving up work. At this time he was a patient at Guy's Hospital under the care of Dr. Hale White, who published a full account of his case.[1] Two years before admission he had entirely lost the use of the right upper limb and the left upper limb became slightly weak. When admitted into the hospital the patient was seen to be a man of very small stature, his height being 56¼ inches. He was very intelligent and had no speech defect. He occasionally had fits, commencing in the right hand, in which consciousness was lost late, the convulsion becoming general, with biting of the tongue and enuresis. He was extremely deaf to both aerial and perosteal conduction, but otherwise the special senses and cranial nerves were normal. The pupils were equal and reacted normally. There were slight nystagmus and slight weakness of conjugate deviation of the eyes on looking to the left. There was no optic neuritis, headache, or vomiting.

Cranium.—The head was much flattened vertically and it was very broad, there being a roll-like projection which commenced in the upper and posterior part of the temporal fossa on each side and ran backwards, overhanging the ears and becoming more and more prominent until it involved the whole occipital region. This projected backwards and downwards, forming a sharp angle with the neck, which did not disappear when the head was fully flexed on the neck. It was as if the posterior two-thirds of the vertex of the skull had been telescoped on to the base by pressure from above, leaving this remarkable calvarial fold along the line of bending. With the face vertical the posterior part of the skull projected backwards 7·5 centimetres from the posterior mid-line of the neck. The upper part of each pinna was pushed down almost to the horizontal, and the lumen of each external auditory meatus was much reduced in size. The deformity of the skull was symmetrical. There was neither deformity nor asymmetry of the face (Figs. 1 and 2).

The patient's height was 4 feet 8¼ inches. The body was well formed and symmetrical, there were no lateral curvature of the spine and no pes cavus. There was slight weakness of the right lower face. The right upper extremity was very rigid, the elbow being pressed into the side and flexed at a right angle, and the fingers were rigidly flexed into the palm. The rigidity was chiefly muscular, but there were adhesions with grating on passive movement in the shoulder and elbow joints. There was marked wasting of all the muscles with no change in electrical reaction. There was complete paralysis of the fingers and wrist, but the patient could flex and extend the elbow and could move the shoulder feebly and slowly. The left upper extremity presented no abnormality. Power in the lower extremities was good, the muscles were well developed, and there was no ataxy. The man walked with a slight limp and had done so ever since the fracture of the right femur in childhood. He complained of no pain. Sensibility to touch, to pin-pricks, and to heat and cold was carefully tested over the right upper limb, and the rest of the body was roughly tested with touches and pin-pricks, but no abnormality was found. There were no sphincter trouble and no vaso-motor or trophic disturbance. The knee-jerks were brisk, the right arm jerks were exaggerated, and the left were present. There was no foot clonus. The plantar reflexes were extensor responses.

On April 10th Mr. Horsley opened the skull over the right arm centre. The bone was found to be very thin and tough and there were apparently several separate bony masses in connexion with the inner surface of the dura mater, which showed white through it. Enough of the calvarium was taken away to allow of the removal of the bony masses at a subsequent operation. The wound was then closed without the dura mater having been opened. The patient was under the anæsthetic (chloroform) for 35 minutes. He recovered well from the anæsthetic, but three hours later his respiration suddenly became embarrassed and he became cyanosed. Stimulants and artificial respiration were at once resorted to and the wound was opened, but no hæmorrhage had occurred. He rapidly became unconscious and he died about ten minutes after the respiratory failure had set in.

Post-mortem examination.—Permission to examine the thorax and abdomen was not obtained. The right shoulder-joint and inter-phalangeal joints of the right index finger were examined and no adhesions or other abnormalities were found. The spine was normal. On removing the spinal cord and dividing it below the medulla a large central cavity was seen lined by a smooth membrane. On opening the skull the dura mater, which was not adherent to the convolutions, was found to be much thickened, especially at its junction with the tentorium, and was of a dark colour. Over the whole of the left parietal region it was hard and contained several eggshell-like bony plates, the largest of which measured 8 centimetres by 6 centimetres, and was situated over the central convolutions. The brain, of a similar peculiar shape to the skull, was soft, and after hardening in formalin it showed no other abnormality than slight dilatations of the lateral ventricles, especially at the anterior horns.

Microscopical examination.—The cavity in the medulla and spinal cord was first noticeable in transverse sections, immediately below the inferior olive on the left side. Traced downwards it became rapidly larger, and in the upper cervical region it measured 10 millimetres in the transverse and 2 millimetres in the antero-posterior direction. It attained its maximum size at the fifth cervical segment, below which level it became smaller and occupied the posterior horn on the left side and disappeared at the level of the eighth cervical segment to reappear at the fourth dorsal segment in the left posterior horn. It disappeared at the sixth dorsal segment. From the medulla to the sixth dorsal segment the cord was much flattened, but below this level it was of normal appearance. The large cavity in the cervical region

[1] Brit. Med. Jour., 1896, vol. i., p. 1377.

was lined by columnar epithelium; the smaller cavity in the left posterior horn had no such lining, but was surrounded by a simple structureless membrane. The cortex of the left central convolutions was normal. A few recently degenerate fibres were found in either pyramid, and more numerous recently degenerate fibres were seen in the antero-lateral tracts of the cord. There was marked old degeneration in the right pyramid, which could be traced down as far as the lumbar region. No abnormality was found in the nerve cells by Nissl's method.

FIG. 1.

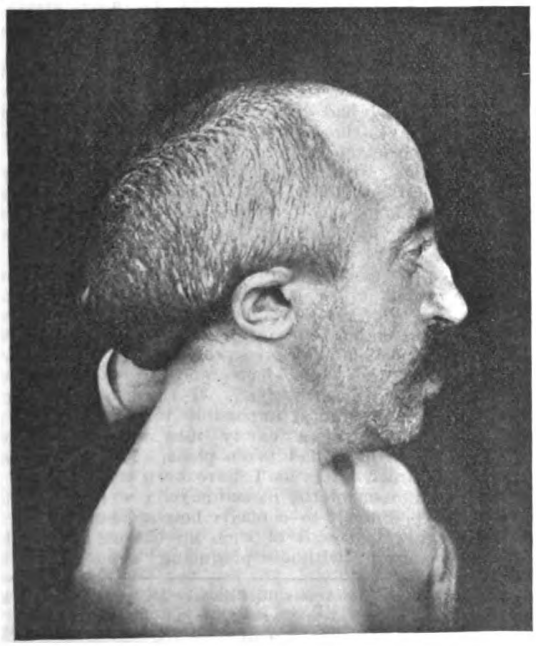
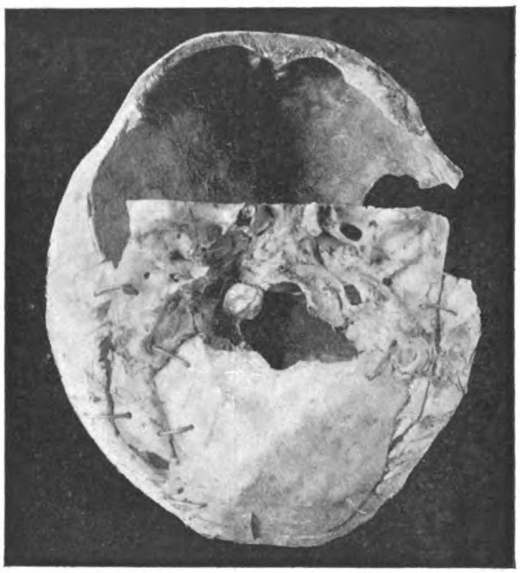
FIG. 2.



Side view of head, showing deformity posteriorly.

Description of the macerated skull.—The whole skull was very shallow, its maximum height when resting on the table being 12 centimetres. It was very broad, the breadth increasing abruptly at the coronal suture, and being greatest in the region of the parietal eminences (Figs. 3 and 5).

FIG. 3.



Macerated skull seen from below, showing the flattening of the base and the abnormal breadth.

The maximum breadth was 17 centimetres and the maximum length was 20 centimetres. The posterior extremity of the skull was the lambda which projected sharply as a broad blunt beak (Fig. 4). The base was extremely large and flat and it included the whole of both squamosal bones and almost the whole of the occipital bone. The external auditory meati, which looked directly downwards, were situated 5 centimetres internal to the lateral edge of the base of the skull. In the centre of the base was a large depression, 7 centimetres by 6 centimetres, in which were situated the foramen magnum, occipital condyles, and basi-occipital bone, with the anterior condylar

FIG. 4.

Macerated skull seen from the side, showing the projection in the lambdoid region.

and posterior and middle lacerated foramina. The shape of the whole skull may be compared with that of a mushroom from its round shape, its flat base with central depression and the overhanging bluntly rounded edge at the junction of the vertex and base. The bony processes at the base were poorly developed. The superior surface of the base showed a marked projection corresponding with the above-mentioned depression. Seen from within, the junction of the vertex and base formed an acute angle from the spheno-squamosal suture backwards. The line of this angle extended from the uppermost limit of the parieto-squamosal suture on either side to the lambda. The mastoid and pterygoid processes were very small. Large anterior and posterior interparietal bones were present. The parietal bones were unduly large, whereas the occipital and temporal bones were very small. Along the line of the coronal suture were several large Wormian bones, and in the squamo-parietal and occipito-parietal suture were hundreds of Wormian bones forming a continuous band from 3 centimetres to 5 centimetres broad (Fig. 6). In the lower parietal region, in the squamosal region, and in the ex-occipital region the bones were very thin, but in the region of the sagittal suture and in the frontal and lambdoid regions they were of normal thickness.

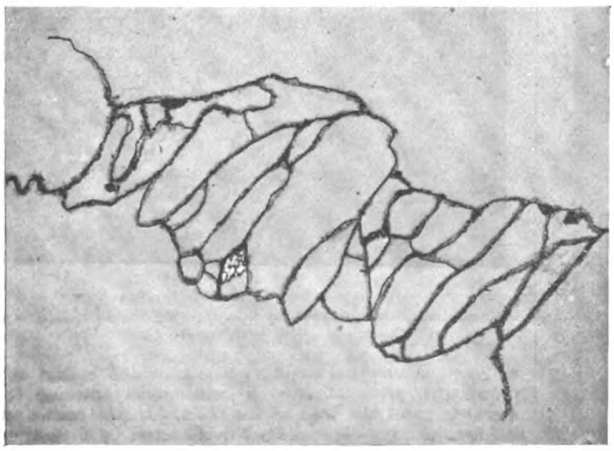
There are several points of considerable interest and still greater difficulty in this case:—

1. The usual signs of syringomyelia were absent, though it must be allowed that the examination of sensibility was not sufficiently thorough to exclude absolutely the presence of some sensory change. While fissuring and central gliosis of the spinal cord are not rarely met with in the absence of symptoms, they are found most commonly in children and are accompanied by little or no distension of the cavities present. Absence of the usual symptoms, where there is such distension of the spinal cord as occurred in this case, is very rare. Baumler[2] collected 25 recorded cases in which the syringomyelia was not discovered till the necropsy, but in only a few of these cases was the clinical record complete. Turner and Mackintosh[3] record a case with necropsy in which, as in this case, there was left hemiparesis without local muscular wasting, but in this case the condition of sensibility was orthodox.

2. Deformities of the skull appear to be rare in cases of syringomyelia and in most of the recorded cases the deformity has approached to the acromegalous type.[4] In some of these other signs of acromegaly have existed, and since enlargement of the pituitary body has been found in several cases where this deformity existed it is considered that in these cases syringomyelia and acromegaly occur together.[5] Dr. W. S. Colman[6] and Westphal[7] have drawn attention to bossing of the frontal and parietal eminences and prominence of the forehead in syringomyelia. During the last three years four cases of syringomyelia in the wards of the National Hospital for the Paralysed and Epileptic presented marked cranial deformity, which was said to have come on after the symptoms of syringomyelia were declared. One of these patients had well-marked signs of acromegaly and the deformity of the skull was of the acromegalous type; the other three cases presented steep overhanging foreheads with frontal and parietal bosses, closely corresponding to Dr. Colman's description. In two of the cases the diagnosis was verified. Owing to the severity of the pain laminectomy and puncture of the spinal cord, to relieve pressure, were performed with the most successful result.

The skull in this case presented features altogether different from those just mentioned, and since the deformity was plainly visible at the age of five years and had not appreciably altered, to the patient's knowledge, since that time, one is led to look for the cause of the deformity in the severe injury which had occurred in infancy. The calcified plates in the dura mater might also have resulted from hæmorrhage occurring at the time of this injury. Could the condition of syringomyelia have been caused by this injury? The cavities in the cord involved the posterior horns—regions where hæmorrhage takes place most commonly and spreads most easily in the spinal cord. A lining membrane of columnar epithelium present in the upper cavity and absent in the lower cavity of this spinal cord is said to be no criterion as to the mode of origin of such cavities. Cases in which typical progressive syringomyelia developed from hæmatomyelia are on record and have been verified. In these cases, however, it seems almost impossible to exclude the pre-existence of a cavity into which subsequent hæmorrhage had taken place. Moreover, in such recorded cases as I have been able to find the symptoms of the hæmatomyelia were permanent. It is difficult to conceive how a hæmorrhage into the spinal cord of such an extent should have occurred without producing some permanent

FIG. 6.



Some of the Wormian bones in the lambdoid suture. (Natural size.)

alteration of the functions of the spinal cord, and this patient led an active artisan's life for 15 years, having no signs of paraplegia. Another difficulty present is that no local pathological condition in the brain was found to account for the occurrence of the localised epilepsy.

It has been several times noted that some patients with syringomyelia bear operations and anæsthetics badly, and in a few reported cases, as in this one, an unexpected and rapid fatal result has occurred.

Wimpole-street, W.

FILARIASIS AND ITS CONSEQUENCES IN FIJI.

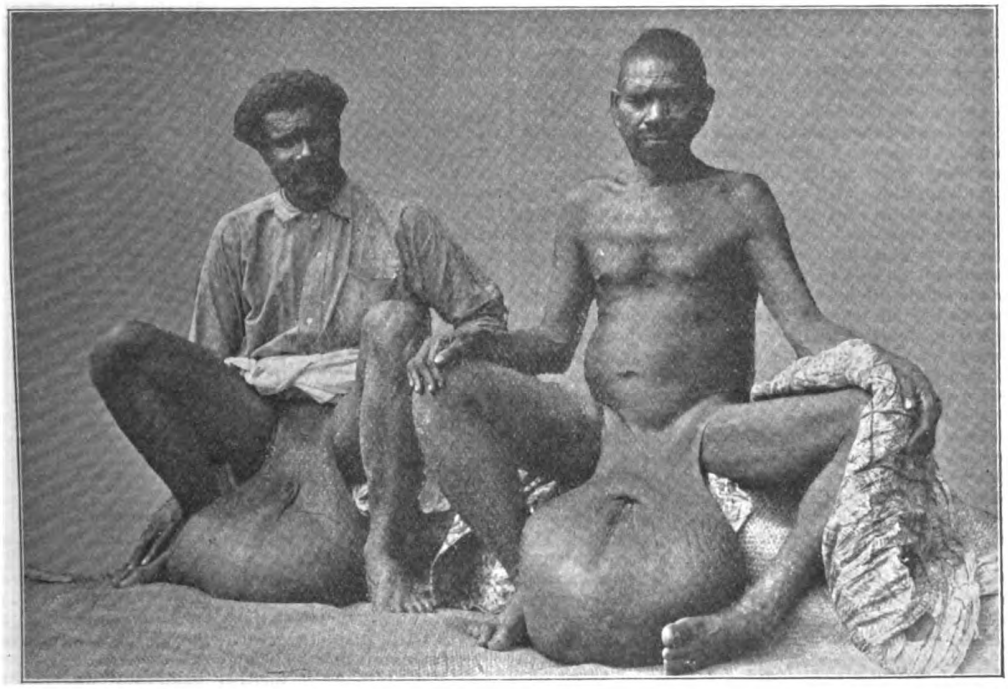
By MORGAN I. FINUCANE, M.R.C.S. Eng., L.S.A., F.R.G.S.,

GOVERNMENT MEDICAL OFFICER AND PROVINCIAL INSPECTOR OF THE PROVINCES OF TAILEVU AND RA.

THE prevalence of filariasis amongst natives and Europeans and its commonest result, elephantiasis of the scrotum, in the South Seas, and especially in Fiji, lead me to think that a description of the operation as usually performed in the Colonial Hospital at Suva, Fiji, would be of interest to your European readers. The illustrations[1] which accompany these notes will show the formidable nature of the condition.

The patient being placed under deep anæsthesia—chloroform is invariably used in Fiji with good results—the scrotal tumour is well lifted up by an assistant and an Esmarch's elastic tourniquet is tightly pulled around the base or pedicle of the tumour; a couple of turns are necessary. The ends of the elastic tourniquet are brought obliquely across Poupart's ligament above the crest of the pelvis to unite behind or at the side, and undue pressure is prevented by padding near the various bony points with cotton-wool. There is now before the operator a huge scrotal mass, in the upper and central portion of which there is a circular depression, the preputial orifice, at the bottom of which is the penis deeply buried in the surrounding elephantoid growth. The index finger of the left hand is now introduced into this circular opening and the glans penis is felt. A curved, blunt-pointed bistoury is now passed along a grooved director or the finger above the glans penis, which is thus avoided, and the skin and subcutaneous tissues freely divided for from one and a half inches to two inches. The glans penis is then seized and drawn forward and isolated and a No. 8 silver catheter is passed, an assistant holding the penis well dragged forward on the catheter and raised towards the abdomen. The penis is then dissected out, the surgeon removing freely all elephantoid prepuce and in clearing it the catheter acts as a safe guide in avoiding the urethra, a wound of which might readily be made in its absence. When this is completed the penis with catheter *in situ* is held well up by an assistant over the abdomen. A long incision is then made from the external abdominal ring over the centre of each testicle almost to the lower margin of the scrotum. A largish strong scalpel or small-sized amputating knife will be found best for dividing the large, thick, and indurated elephantoid scrotum which is so commonly found in chronic cases coming for operation. A free cutting incision must be made the whole length of the first skin incision. Numerous transverse fibrous bands will be met with and require division, and the knife, if not firmly held, will be apt to slip, as there is a continuous exudation of varying quantities of serous and blood-stained fluid. The tunica vaginalis being readily recognised is freed at its lower end and dissected out with its contents by a process of tearing and cutting. Some care is required in dissecting out the cord and removing masses of elephantoid gelatinous tissue adhering to it; a few large veins also sometimes require ligature. It is very rare to find cases of elephantiasis requiring operation in which there is not a hydrocele. In fact, as a rule the hydrocele is very large, accounting in a good many cases for the size of the tumour.

It is now necessary, having dissected out both testes and cord right up to the external abdominal ring, to evacuate the contents of the hydrocele with a trocar and canula, afterwards cutting away the thickened elephantoid tunica vaginalis, leaving only the testis and cord on each side. Both testes being held up over the abdominal wall, the operator proceeds to fix the base of the tumour by skewers introduced as high up as possible, so as to avoid all



Two typical cases of elephantiasis of the scrotum.

[1] We have selected for reproduction one from the many interesting photographs sent to us by Mr. Finucane.—ED. L.

elephantoid tissues, but immediately below the tourniquet. He passes the point of the skewer transversely across the perineum, guided by his left index finger. He carefully avoids the urethra which might easily be transfixed if care were not taken and he makes the point emerge as high as possible on the opposite side at a point corresponding to the entrance wound. A strong cork is then put on the point of the skewer to avoid injuring the left leg. The second skewer is introduced on the left side and as near the posterior part of the perineum as possible; it is similarly dealt with and secured on the right side by another cork. These skewers act as a hold on the perineal skin after division of the tumour and prevent retraction of the mass and play an important part in preventing hæmorrhage; in fact, the removal of the largest elephantiasis can be carried out in an almost bloodless way if this course is pursued. The surgeon then divides the tumour about a line's length below the lower skewer, cutting freely through the growth in front and working circularly around the tumour, dividing last the retracting perineum. Were it not for the skewers on removal of the growth the retracting perineum would slip through the Esmarch's tourniquet and considerable hæmorrhage delay the completion of the operation. The vessels are now picked up one by one and tied at once, in largish tumours as many as 20 or 30 being met with requiring a ligature. The skewers are now removed, the tourniquet is loosened, and general oozing is dealt with, of which sometimes there is a considerable quantity from enlarged veins about the testes and cords. The edges of what is really part of the perineum and inner sides of the thigh are now brought together and the paucity of skin is sometimes alarming, leading the operator to fear whether he may be able to accommodate the now swollen testes. The skin, however, here is readily adaptable and a good scrotum can always be fashioned.

In native Fijians it is rarely necessary to drain the new scrotum; wire and silk sutures are put in the whole length and as much of the denuded penis covered up by surrounding healthy skin as is possible. Healing of the scrotum by first intention is the rule, but owing to the necessity of granulation of the penis the recovery in Fiji after this operation is rarely completed under three months. In operating on an elephantiasis of the scrotum the possible presence of a hernia complicating matters must be carefully borne in mind. It is not a common experience in Fiji, but nevertheless does occasionally occur. Fijians as a rule do not come for operation until the growth is large and it is unusual for any to be seen in the Colonial Hospital under 10 lb. in weight, and some cases have been enormous, one recorded by Sir William McGregor weighing 100 lb.

As to the clinical history of filariasis and its results in Fiji, it is prevalent all over the Fijian group and attacks every race, being, of course, more common among native Fijians. It is to be seen in its most virulent forms in low-lying, swampy districts, such as on the Rewa Delta. It is almost impossible to find an adult person free from elephantoid enlargement of some portion of the body in the coast towns of Ra province, and it is extremely common in the mountain villages of Colo in Viti Levu. Needless to say, bush, town swamps, stagnant water, and mosquitoes abound in all Fijian villages.

Cutaneous and deep lymphatic varix and orchitis, lymph scrotum and elephantiasis, are all to be met with in varying stages of the disease. Elephantoid enlargement of the leg, the arm, and the breast is very common amongst Fijian women, and the disease is occasionally met with attacking the vulva. Every growing Fijian child suffers periodically from "wagaga," which is simply an attack of lymphangitis, generally occurring in an extremity, an arm or a leg, but most frequently in the male it affects the testicle or cord, suggesting a commencing "epididymitis." With this "wagaga" there is fever, headache, and general malaise. It is not common to be able to define or see the inflamed lymphatic cord in the native, though amongst Europeans and half-castes it is nearly always noticeable. The commonest result in these cases is the formation of an abscess which terminates the attack, and the patient returns to his ordinary health to await another outburst of filariasis, most Fijians being liable to four or five such attacks annually. It would be rare to find a Fijian who did not bear on his body the many previous scars of former filarial abscesses, either opened by a surgeon's knife or by the natural process of suppuration, or more commonly as the result of his own incision by a sharpened bamboo. The character of the abscess is small and circular, and on excision there exudes thick, creamy pus, followed by a small clot or flow of blood, suggestive of embolic plugging of an area of capillary or lymphatic tissue. Other cases I have seen where the lymphangitis stopped short of suppuration, producing diffuse matting together of the tissues of the abdominal wall, and where the patient passed rapidly into a septic condition and died. In the earlier stages, before any local symptoms show themselves, these cases are extremely puzzling and much resemble the remittent form of malaria, a disease happily almost unknown in Fiji.

The chronic variety of filariasis producing elephantiasis is next to abscess the commonest form in Fiji and for it the operation described above has to be frequently performed. Chyluria is rare in Fiji and the filarial attacks more commonly result in the other conditions already described.

Quinine is given with good effect in acute filarial attacks and at the same time local remedies are employed.

A CASE OF MOLLITIES OSSIUM WITH SPONTANEOUS FRACTURE THROUGH THE GREAT TROCHANTER OF THE LEFT FEMUR.

BY J. HOGGAN EWART, M.D. EDIN.

THE following case presents many points of interest.

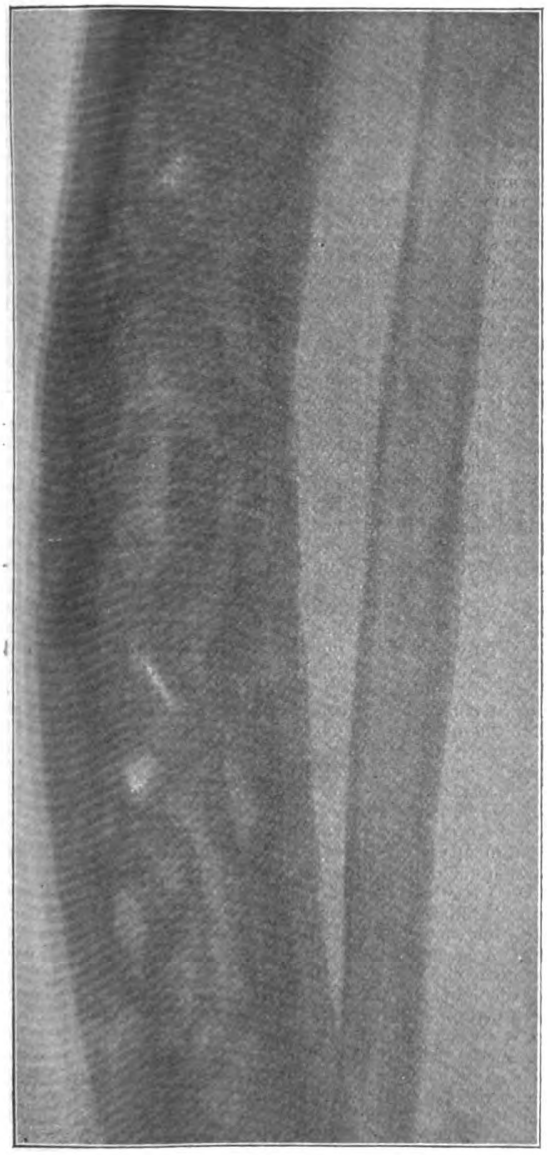
The patient was a widow, aged 65 years. Her mother had died from cancer at the age of 50 years. There was no history of bone troubles in the family. The patient had always had very comfortable surroundings. She had had no severe illnesses, but had suffered from menorrhagia for several years and a polypus was removed from the uterus 14 years ago. She had had 10 children, but with the exception of the first confinement, which was tedious, there was nothing to note. She had always led a very active life. 14 years ago she first noticed that her left ankle was thicker than the right, and she showed it to a medical man who told her not to worry, and she left it alone for two years, when she showed it to Dr. Douglas of Newbury, who has kindly sent me a note to the effect that she consulted him for rheumatism and he discovered a yielding of the tibiæ and warned her that if she persisted in walking she would find herself with broken bones. She did not trouble herself much, but gradually she noticed that the right shin-bone was becoming very bent like the left. However, she managed to get about with the help of a stick. On March 1st last she suddenly felt a pain in the upper part of the left thigh and associated it with a small lipoma which had existed for years. The pain increased and she saw a medical man who told her that it was rheumatism and ordered hot fomentations and massage, but on March 15th while walking with a stick and leaning on her daughter's arm they both heard a crack and the patient subsided on to the ground. I saw her shortly after the accident and diagnosing an extra-capsular fracture of the left femur put the limb up on a Liston's long splint with weight extension and gave a very guarded prognosis. I noted great deformity affecting the left side of the pelvis, both femurs, and both tibiæ; all the other bones, however, were normal. The urine showed a marked increase in phosphates. About three weeks after the accident a skiagram was taken (see Fig.), which showed the fracture which had taken place through the great trochanter of the left femur. The splint was removed at the fifth week and sand bags were substituted.

At the ninth week another skiagram was taken which showed that the fracture had united with osseous union, a large amount of callus having been thrown out. This condition could also be verified by manipulation. A third skiagram was taken which showed the deformity affecting the left tibia (see figure). This skiagram is interesting in that it shows the effect of the disease on the texture of the bone. It will be seen that the tibia is more pervious to the x rays in some parts than in others, so that it presents a mottled appearance. The fibula appears to be unaffected. (Note that the fibula should normally appear as a shadow over the length of the tibia, the skiagram having been taken from the inside.)

The patient is now (11 weeks (?) after the accident) able

to go out in a chair and suffers no pain. She does not put any weight on the legs for fear the tibiæ might give way.

The following measurements are worthy of note. Left leg: from the anterior superior spine to the internal malleolus, 30½ inches; from the anterior superior spine to the ischial tuberosity, 11 inches; circumference at the knee, 14 inches; at the calf, 11¼ inches. Right leg: from the anterior superior spine to the internal malleolus, 31½ inches; from the anterior superior spine to the ischial tuberosity, 10 inches; circumference at the knee, 13¼ inches; at the calf, 10¾ inches. Interspinous, 14 inches.



The osteo-malacious left tibia. The skiagram has been taken from the inner aspect of the limb, as is obvious from the relation of the bones to each other.

The special points in the case are (1) the duration of the disease (14 years) with so little discomfort; (2) the small number of bones affected—viz., the left side of the pelvis, both femurs, and the tibiæ; and (3) the age of the patient (65 years) and the fact that callus was thrown out and union occurred in nine weeks.

My thanks are due to Mr. Stainer of this town who kindly took the skiagrams.

Folkestone.

A CASE OF COBRA-POISONING TREATED WITH CALMETTE'S ANTIVENINE.

BY W. HANNA, M.A., M.B. R.U.I., D.P.H. CANTAB.,
AND
GEORGE LAMB, M.B. GLASG.,
CAPTAIN, I.M.S.
(From the Research Laboratory, Bombay.)

THE following record of a case of cobra-poisoning is of interest inasmuch as the identity of the snake was without doubt. All the symptoms were carefully noted from the beginning, and the only treatment employed was the injection of Calmette's antivenine.

On Oct. 6th, 1900, one of us was assisting in the extraction of poison from a full-sized cobra. Before proceeding to compress the glands in order to expel the poison the operator was clearing away some mucous secretion from the neighbourhood of the mouth. This was being done with a small piece of cotton-wool held in the naked hand. The snake at the time was firmly held just behind the head in the hand of an experienced native snake-man. By some means or other the snake buried its right fang through the cotton-wool into the point of the operator's right thumb. The thumb was withdrawn practically instantaneously, but, as the after-history will show, not before a considerable quantum of poison had been injected. It is worthy of note that immediately afterwards four large drops of venom were pressed from the left gland, while none was obtained from the gland of the opposite side. As the wound was at first considered to be a trifling one, and as the snake was not believed to have injected any poison, no local treatment was employed except sucking the wound. This was done thoroughly and free bleeding occurred.

On the advice of Mr. Haffkine, at from 20 minutes to half-an-hour after the bite 18 cubic centimetres of Calmette's antivenomous serum were injected, half into each flank. This serum, which was from four to five years old and had been in Bombay as the property of the Bombay Natural History Society for about four years, was the only serum available at the time. It may be stated here that some experiments on rats, made by us some few days previously to the accident here recorded, had shown this serum to have deteriorated to such an extent that it only retained about one-fourth of the neutralising power which Calmette's standardisation had ascribed to it. These experiments, along with others which are at present in progress, will form the subject matter of another communication. About two and a half hours after this dose of serum had been administered some general symptoms of cobra-poisoning referable to the nervous system set in. In chronological order these were as follows. There were first disinclination to work and lethargy, and then followed nausea and vomiting, accompanied by slight paresis of the legs. While these symptoms were still present some fresh serum, dated May 8th, 1900, was procured. Ten cubic centimetres of this were at once injected into the left flank; that is, about three and a half hours after the bite. Nausea and weakness of the legs continued for some time. From two to three hours, however, after the second dose of serum all symptoms had passed away.

Locally at the moment of injection there was much pain at the site of the wound. This pain increased and was soon followed by considerable swelling of the whole of the thumb, which in a few hours became exceedingly tense and very painful. There was much extravasation of blood into the tissues around the puncture, while a bloody exudation oozed out from the wound for 24 hours at least after its infliction. During this time also there were pain and tenderness along the tract of the median nerve into the axilla; tenderness was especially well marked at the bend of the elbow and in the axilla. There was also some anæsthesia of the anterior surfaces of the three and a half outer fingers, the superficial finger distribution of the median nerve. There was neither enlargement nor tenderness of any of the lymphatic glands. It soon became apparent that a slough was going to form round the site of inoculation. This slough became demarcated in a few days. It was of the size of a threepenny-piece. It came away in about three weeks' time and left a hole a quarter of an inch deep. This wound has

gradually granulated up and now (six weeks after the accident) it is nearly healed.

The case is an interesting one and worthy of record as one in which the identity of the snake was beyond doubt; and further, the case was under observation from the first, and symptoms, both local and general, were carefully noted as they appeared. It also points to the efficacy of Calmette's serum when fresh, even when general symptoms have appeared and in spite practically of no local treatment, not even a ligature.

The following conclusions can be drawn:—1. That great care is required in handling poisonous snakes. 2. That the puncture of a fang of a passive snake is not to be neglected, as a considerable amount of poison may be forced out from the gland through reflex action, initiated by simple pressure on the fang. 3. That thorough sucking of the wound is of little avail as a local treatment; the poison lies deep, is viscid, and the bleeding in all probability takes place from superficial vessels. 4. That it is advisable to keep a stock of *fresh* antivenomous serum in dispensaries in India, and the use of this serum is not to be neglected even after general symptoms have set in.

Bombay.

MEMBRANOUS ŒSOPHAGITIS;

EXPULSION OF A COMPLETE CAST OF THE ŒSOPHAGUS.

BY NATHAN RAW, M.D. DURH., F.R.S. EDIN.,

MEDICAL SUPERINTENDENT OF THE MILL-ROAD INFIRMARY, LIVERPOOL.

(*With Coloured Illustration.*)

THE following most remarkable case occurred in a man aged 46 years, a labourer, who was admitted into the Mill-road Infirmary, Liverpool, on April 10th, 1900, complaining of pain beneath his sternum and difficulty in swallowing. For several years he had been a heavy drinker and had always drunk neat whisky, which invariably caused a burning sensation in his throat and down the line of his œsophagus. During the last six months he had had increasing difficulty in swallowing solids, and on admission to the infirmary he could only swallow fluids. When asked why he continued to drink when it caused him pain he replied that it gave him a "feeling of satisfaction," that the neat whisky did him good. On April 16th after a violent fit of coughing he vomited a complete cast of his œsophagus eight and a half inches long. It was very foul-smelling and of a dirty greenish appearance. The nurse stated that he nearly choked in endeavouring to expel it, but that he seized it with both hands and dragged it out.

Etiology.—Inflammation of the œsophagus is caused by the immediate contact of irritants swallowed, especially hot liquids, corrosive fluids, and by the continued action of irritating substances repeatedly swallowed, such as strong alcoholic drinks (Fitz). In this case the patient had practised a foolish custom (only too prevalent in Liverpool) of drinking neat brandy and whisky and at times rum, more especially in the early morning.

Morbid anatomy.—Follicular, fibrinous, and diphtheritic inflammations of the surface of the œsophagus occur, whilst still another variety is the phlegmonous inflammation of the connective tissue of the wall. I am inclined to think that my case is one of the latter variety.

The number of cases on record of this rare disease is very few and I have only been able to find five others, and no previous case in this country has, so far as I know, been described.

The condition known as exfoliative or desquamative inflammation of the œsophagus, or by the term most recently applied, "œsophagitis dissecans superficialis," was first described by Birch-Hirschfeld in Ziemssen, vol. viii., page 140. In this remarkable case a woman vomited a complete cast of her œsophagus, which on examination was found to consist of the epithelial layer infiltrated with round cells. In Reichmann's case this epidermoid layer was free from leucocytes, whilst Fitz records a similar condition which was exfoliated from the gullet of an infant who had taken a dose of chloral. Rosenberg reports a case where the mucous membrane was both streaked with blood and infiltrated with leucocytes. Sclavunos reports a fifth case in which the epidermic tube was inverted.

Phlegmonous œsophagitis is a suppurative inflammation of the submucous layer. A circumscribed abscess in the submucous tissue results or the pus completely encircling the œsophagus may follow its length even to the stomach (Fitz). After separation of the slough healing takes place, scars result, and if the corrosion has extended to the muscular coat, extreme, or as in the present case complete, stenosis follows.

Symptoms.—On admission the patient was a thin spare man, having the appearance of recent emaciation. His weight was exactly 100 lb. Six months previously he first noticed some difficulty in swallowing solids. Lately he had noticed that anything of a solid nature seemed to stick at the lower part of his œsophagus, although he never had any regurgitation of food. Cold liquids produced pain during transit and for this reason he had taken warm drinks. On April 1st he vomited a large quantity of blood-stained fluid. On admission he had tenderness on pressure along the line of his gullet and pain of a diffuse nature, especially on attempting to swallow. Stricture or some malignant disease was suspected, but a soft rubber stomach-tube passed quite easily into the stomach without pain or discomfort. He preferred the upright position and always sat up in bed with his head fixed and rigid. A diagnosis of spasm of the œsophagus with alcoholic gastritis was made and he was fed on carefully warmed nutritive fluids.

On April 16th, or six days after admission, he had a violent fit of coughing and after some difficulty he vomited up a complete cast of his gullet, the patient himself forcibly pulling it out of his mouth.

The cast weighed two and a quarter ounces, was of a dirty-greenish appearance, and was streaked with a purulent coating of blood-stained pus. The smell was most offensive and some disinfectant had to be added at once. It had all the appearance of a complete œsophagus, but on examination the muscular layer was not present. The patient coughed and vomited up a good deal of purulent matter and seemed much relieved, but the pain on attempting to drink any fluid was so intense that he was afraid afterwards to try. He was fed on nutrient enemata for two or three weeks, when he again was able to swallow some fluids without much pain, but was only able to get down a very small quantity at once. He was losing flesh rapidly and it was quite evident that he had considerable stenosis of his gullet and that it soon would be complete. Accordingly it was thought desirable that if the operation of gastrostomy was to be performed it had better be done whilst he had some strength to bear it. He readily consented.

Operation.—Under ether on May 12th the usual incision was made for gastrostomy by Albert's method. The stomach was found to be retracted and collapsed, and it was with some difficulty that I was able to draw out a long conical diverticulum of the anterior wall. The parietal peritoneum and the posterior layer of the sheath of the rectus were then sutured around and through the walls of the stomach down to the mucous coat, and the suture was pulled moderately tight. A second small incision was made above and on a level with the costal cartilages and the skin was separated from the subjacent parts. The diverticulum of the stomach was drawn up under the skin to the second incision, and its apex was fixed with a few sutures after a small opening had been made into the stomach and a rubber tube inserted. The first incision was then completely closed and covered with gauze and sealed with collodion. The patient was fed at once with one pint of milk, beef juice, and some brandy through the tube, as he was rather collapsed.

The operation was quite successful, as the incision healed by first intention, and the sutures were removed on the eighth day. He recovered nicely for a time and was able to feed himself regularly, but three weeks after the operation he commenced to regurgitate large quantities of gastric juice followed by the food in a form which except for the curdling of milk did not appear to be altered.

After-progress.—It was evident that despite washing out his stomach regularly with an antiseptic and the most careful feeding he was not able to digest food, and it occurred to me that perhaps the mucous membrane of his stomach and intestine might be similarly affected. He was in addition fed per rectum as he could not swallow at all, there being complete stenosis of the gullet. He accordingly slowly went down hill and died from asthenia six weeks after the operation. His weight at death was 87 lb.

Necropsy.—A post-mortem examination was made 24 hours after death. The body was greatly emaciated. The digestive

organs were removed *en masse* for careful examination. The stenosis of the œsophagus was complete from the upper third right up to the pharynx. Below, down to the stomach, it would only admit a medium-sized catheter. There was no trace of any mucous lining anywhere, except near the cardiac end of the stomach, the cast having separated one inch above the entrance to the stomach. The stomach was small and was firmly united to the skin wound. On opening it one was particularly struck with the apparent absence of mucous membrane; the wall was almost smooth and the rugæ were represented by indistinct lines; very little secreting surface was left and that near the pylorus. There were no evidences of gastritis. The intestines were atrophied and the mucous coat of the duodenum was smooth and thin, though otherwise healthy. There were no other symptoms of organic disease, except some brown atrophy of the heart.

The following description of the cast is by Dr. R. J. M. Buchanan, physician to the Stanley Hospital, Liverpool. "The cast was in the form of a tube, eight and a half inches long, of a greenish-gray colour, and with a smooth but somewhat corrugated external surface. The inner surface of the tube had the appearance of sloughing tissue, and it was ragged and undermined in comparison with the smooth outer surface. The cast was very tough and elastic; it was with difficulty that pieces could be cut from it for microscopical purposes. Portions of it were hardened and dehydrated in absolute alcohol passed through cedar-oil and embedded in paraffin. Sections were cut with the rocking microtome. The tough fibrinous nature of the tissue was rendered very apparent by the resistance which it offered to the microtome knife. The sections were stained with Ehrlich's acid hæmatoxylin and mounted in Canada balsam.

Microscopical examination showed that the cast was a complete slough of the inner layers of the œsophagus as far as the muscularis externa. The superficial epithelium had almost entirely disappeared in the deeper parts of the folds of the mucosa. A very few degenerated cells remained which were scattered in patches. Small ulcerations of the mucosa, in the form of flask-shaped pits, were completely filled with micrococci and rod-shaped bacilli. The denser tissue immediately beneath the epithelial layer had retained its characteristic structure in parts, but was broken through by the small ulcerations extending from the surface. The remainder of the mucosa and submucosa was invaded by a fibrinous network filling up the spaces between the degenerate fibrous tissue. This fibrinous network was similar in appearance to a diphtheritic membrane. Here and there could be recognised muscular fibres from the muscularis mucosa. The meshes of the net-work were crowded with leucocytes and rod-shaped bacilli, the latter very varied in shape, which had stained irregularly, similar to the diptheria bacillus. Minute hæmorrhagic extravasations from the vessels had evidently taken place at different times and the remains lay scattered about. The blood-vessels were blocked with thrombi and the lymphatics were dilated with coagulated exudation. The condition revealed by microscopical examination is suggestive of a submucous dissecting cellulitis leading to complete separation of the inner coats of the gullet."

Remarks by Dr. NATHAN RAW.—The case seems to be unique in this country, the few others recorded having occurred in Germany and America. The cause in this case was neat spirits, of which the patient had taken a very large quantity, and yet at the necropsy no evidences of cirrhosis of any organs were observed. The disease had evidently not been confined to the mucous lining of the œsophagus, but had attacked that of the stomach to a minor extent. With regard to the operation of gastrostomy I am inclined to think that Albert's method has no advantages over those of Howse or Witzel, and it is certainly much more difficult to perform, especially if, as in my case, the stomach is small and retracted.

I am much indebted to Dr. Buchanan for the excellent description of the cast and to my assistant, Dr. F. S. Pitt-Taylor, for the after-treatment of the case.

Liverpool.

THE HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, BROMPTON.—It is officially announced that a site for the proposed country branch and convalescent home has been chosen at Heatherside near Bagshot, and the outlay is estimated at £20,000.

LONDON TEMPERANCE HOSPITAL.

A CASE OF PHAGEDENIC CHANCRE OF THE UPPER LIP IN A YOUNG WOMAN; EARLY AND MARKED SECONDARY ULCERATION OF THE PALATE; EXEMPTION OF THE SKIN; REBELLIOUSNESS TO MERCURIAL TREATMENT; RAPID AMELIORATION UNDER IODIDE OF POTASSIUM.

(*With Coloured Illustration.*)

(Under the care of Dr. W. J. COLLINS.)

THE occurrence of phagedæna in a syphilitic sore is to be attributed probably to a secondary local inoculation of a septic organism and not merely to the debilitated condition of the general health. That the general condition, though predisposing to phagedæna, is not its sole cause is shown by the fact that when more than one syphilitic ulcer is present some may become phagedænic while the others may undergo no change. In the following case the improvement under iodide of potassium is certainly remarkable. The situation of the sore rendered it impossible to employ the continuous warm bath which is always so valuable in the treatment of phagedæna.

A young woman, aged 19 years, a domestic servant, of healthy appearance, with a tuberculous history on her mother's side, was admitted into the London Temperance Hospital on Feb. 27th, 1900, with an ulcerated swelling situated in the prolabium of the upper lip. The base of the ulcer which was somewhat of a trefoil shape, was hard and infiltrated, giving the appearance of a conical projection when seen in profile. The surface of the ulcer secreted a little thin pus which tended to encrust and the edges were sharply defined against the red muco-cutaneous surface of the labium. There were enlarged and tender glands below the mandible, more pronounced on the left side; the pre-auricular lymphatics were unaffected. Dr. Collins made a provisional diagnosis of a syphilitic chancre and ordered mercurial inunctions.

On March 21st the ulceration was noted to be slowly extending and the appearance was that of a phagedenic ulcer destroying the tissues of the lip. An examination of the blood for organisms gave a negative result. On the 24th the appearance of the ulcer was described as "crateriform." The temperature continued to be elevated, ranging between 99° and 100° F. and occasionally reaching 101°, and there was much pain in moving the lip; otherwise there were no constitutional symptoms. On April 5th an ulcer appeared on the left tonsil and on the 12th this had extended to the left side of the palate. Despite full doses of mercury externally and internally the condition of the lip was becoming worse rather than better, and the patient's condition was very deplorable. Ophthalmoscopically no change was to be seen and no eruption appeared on the skin.

On May 10th Dr. Collins decided to give up mercury in favour of large doses of iodide of potassium. An improvement was soon apparent in the lip, though the palate showed a sloughing appearance. The submaxillary glands became reduced in size and were no longer tender. On May 19th the edges of the ulcer on the upper lip were becoming healthy and a slough had separated. On the 28th there was rapid improvement. Some deformity of the upper lip resulted. The throat was still ulcerated. On June 19th the lip was well and the throat was now rapidly healing. There were no skin or ocular symptoms. Her general health was greatly ameliorated. On the 22nd the patient was discharged, apparently well. She was ordered to continue the iodide of potassium for a while and to return later for plastic

operation on the lip. Six months later the patient was well and the deformity was much less noticeable.

Remarks by Dr. COLLINS.—No explanation of the source of infection in this case was forthcoming, though it is difficult to doubt the nature of the disease. The extensive phagedæna, the early implication of the throat, the absence of any skin eruption, the rebelliousness to mercurial treatment, and the rapid improvement under potassium iodide are noteworthy features in the case.

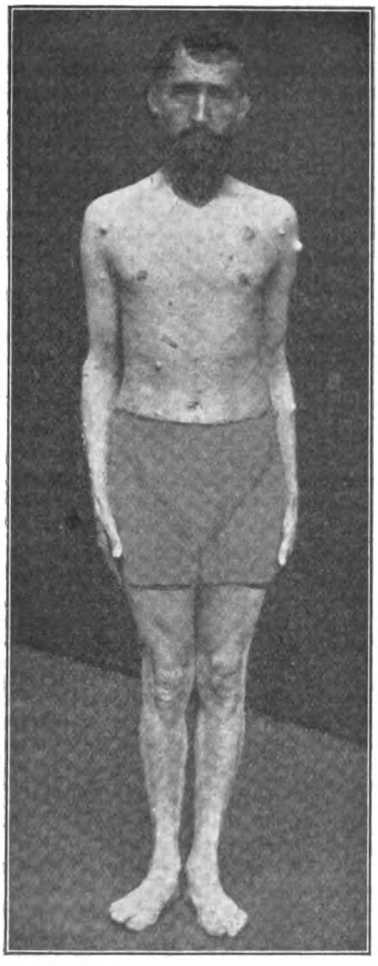
LEEDS GENERAL INFIRMARY.

A CASE OF GENERALISED NEURO-FIBROMATOSIS WITH "FALSE NEUROMA" OF THE VAGUS NERVE.

(Under the care of Mr. B. G. A. MOYNIHAN.)

THERE can be no doubt that in some cases at least the soft pendulous tumours known as molluscum fibrosum are derived from an overgrowth of the fibrous tissue of nerves, but there is much more difficulty in proving that this is the origin of all the cases of molluscum fibrosum. It is not improbable that the fibrous tissue connected with other cutaneous structures may at times be the source of the hypertrophy. In Mr. Moynihan's case a tumour of a special nerve, the vagus, was associated with the general neuro-fibromatosis, and the apparent harmlessness of a resection of a considerable portion of this important nerve is very striking.

FIG. 1.



Front view of the patient.

A man, aged 37 years, was admitted into the Leeds General Infirmary on July 31st, 1900. The patient, who was thin, slightly built, sallow, and of average intelligence, had noticed for the first time a swelling on the left side of the neck about six weeks previously. At that time the swelling was small, "hardly bigger than a nut," but the increase in size had been rapid and steadily progressive. At the time that the lump was first observed he began to suffer from an irritable cough, which was increased or induced by any sudden movement of the neck or by handling of the swelling. Persistent pressure of a collar or long handling brought about violent seizures of coughing with an alarming sensation of choking.

On examination a swelling three inches in length or a little more was felt on the left side of the neck lying over the common carotid artery, partially under cover of the sterno-mastoid muscle. The swelling was smooth, firm, though very slightly elastic, and moveable freely from side to side but not from above downwards. It was well defined and could be lifted from its bed so that the fingers almost met behind it. There was no pulsation in it. Manipulation of the tumour caused great respiratory irritation. During an attack of coughing thus induced, the swelling was found to present prominently in the posterior triangle of the neck. There was no interference with deglutition. The patient's voice was rather hoarse and metallic and was "thyroid" in character.

As regards the general condition of the patient the whole body was covered with soft excrescences, varying in size from that of a pin's head to that of a walnut. Some of these were sessile and others were broadly or finely pedunculate. The larger ones were very soft and suggested the appearance and feel of an almost empty umbilical hernial sac. All were quite irregular in distribution; no method in their arrangement could be conceived. Hair was entirely absent from them all. Over the whole body were irregular patches of pigment, of the colour of *café au lait*. The patches on the face were like pronounced freckles; elsewhere patches of the size of the palm of the hand were observed. Their arrangement seemed to be quite capricious, not following nerve distribution or the placing of the pendulous masses. The pigmentation and the excrescences were present at birth and had altered little or not at all. A careful examination did not reveal any "beading" of the nerves of the upper or lower extremities.

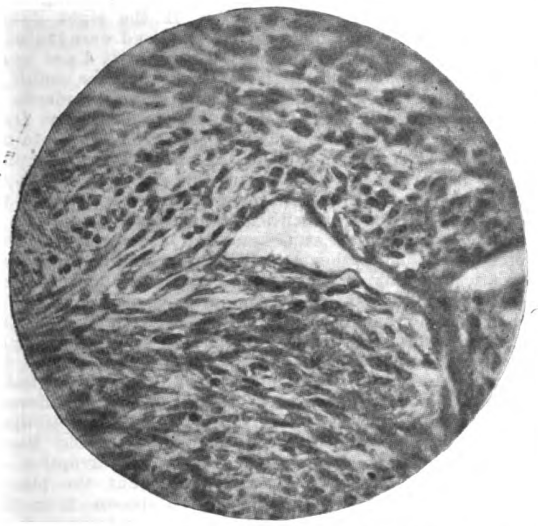
The patient's father, one brother living, and one brother dead, had all been covered with patches of brown pigmentation and soft excrescences such as these. No solitary tumours of the kind noticed in the neck had been noticed.

An incision was made along the anterior border of the sterno-mastoid for four and a half inches and the tumour was exposed. It was found to be fusiform in shape, tailing off at each end into a cord of the thickness of a lead pencil, knotted, gnarled, and tough. This cord extended up to the base of the skull and could be felt to extend downwards into the thorax. The whole of it was beaded in the same irregular fashion. This cord was clearly the vagus nerve in connexion with which the tumour was growing. A ligature was placed on the nerve above and below and the growth, with about three inches of nerve, was removed. After the operation the pulse varied from 80 to 96, the respirations were constantly 24, never varying from that so long as the patient remained in hospital. For 48 hours after the operation complaint was made of acute epigastric pain, but no tenderness or distension was observed. There was no vomiting. The voice was a trifle more husky than before for several days, but eventually returned to its former condition. The wound healed by first intention and the spasmodic seizures of dyspnœa and coughing entirely ceased. The patient left the hospital on Sept. 12th, 1900.

Pathological report by Mr. P. J. CAMMIDGE.—The tumour received for examination on August 10th is smoothly ovoid in shape, and measures 7·5 centimetres long by 5·0 centimetres at its greatest transverse diameter. Attached to either extremity is a portion of nerve, the one being 2·0 centimetres by 0·5 centimetre, and the other 2·5 centimetres by 0·6 centimetre. The tumour is covered by a glistening capsule, which is loosely adherent and easily strips. Shining through the capsule a number of small tortuous vessels are to be seen, but no strands of nerve tissue can be distinguished. On section the capsule appears to consist of loose areolar tissue arranged in layers and varies in thickness from 0·1 to 0·05 centimetre. Several compressed oval strands of nerve fibres lie between the capsule and the body of the tumour, but they are not attached to either and readily shell out. The general colour

of the tumour is a greyish-white, and mingled with this are numerous areas which have a deep yellow tint and some small patches which appear gelatinous and semi-transparent. To one side of the centre is a necrotic area measuring roughly 1·5 by 2·0 centimetres, and consisting of mucoid material mixed with loose fibres, the whole, together

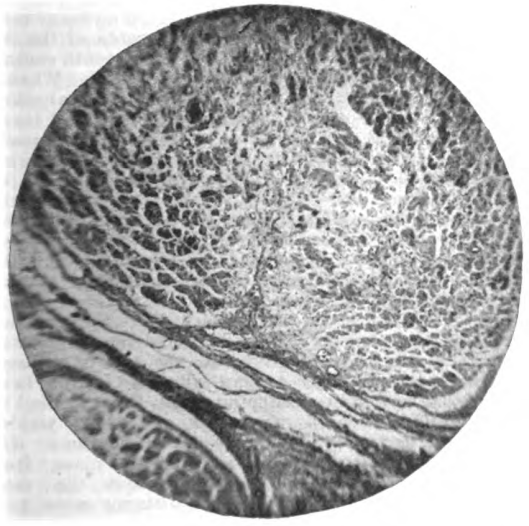
FIG. 2.



Microscopic appearance of the tumour under a high power.

with the tissue for a short distance round, being coloured a deep brown. A few small vessels and numerous points of brown pigment are scattered irregularly over the cut surface, but the collections of pigment are especially numerous in the neighbourhood of the capsule. The fibres of which the tumour is composed are arranged in whorls and

FIG. 3.



Microscopic appearance of the nerve trunk under a low power.

the yellow areas mentioned above are seen to be chiefly situated toward the centres of these whorls.

Microscopically the body of the tumour is composed of spindle-shaped cells, with large oval nuclei, closely packed together. Some are seen in transverse and others in longitudinal section; the arrangement of bundles and whorls noted with the naked eye is also seen microscopically. Numerous thin-walled vessels and blood spaces, lying in intimate contact with the cells, are scattered through the section. In the neighbourhood of these, and in places apart from any vessels, are patches of extravasated coloured corpuscles, such patches being more numerous in sections taken from near the capsule. Scattered patches of cells do not take the stain well and the nuclei are either indistinguishable or only faintly stained; a large number of cells are to be seen also which, although staining fairly well, are very granular and contain a large number of small fatty granules scattered through the protoplasm. These degenerate cells, as a rule, are more numerous about the centre of a whorl of more healthy cells. Most careful and repeated staining by Weigert's method has failed to reveal any nerve fibres in the body of the tumour. The capsule consists of loose areolar tissue in which are embedded numerous small blood-vessels, often surrounded by more or less extravasated blood which frequently extends widely into the surrounding areolar tissue.

Sections of the nerve bundles lying between the capsule and the tumour show marked fibrosis affecting both the endo- and peri-neurium, but chiefly the former. In places the increase of fibrous tissue is very marked, the nerve fibres being separated and surrounded by a well-marked ring of the new tissue; in others the increase is less marked, and in others again the appearance is almost normal. Unusual numbers of blood-vessels are also to be seen. In the nerve trunks connected with the tumour the epineurium appears to be slightly thickened and blood-vessels are more numerous than normal. In the perineurium there is some increase of the concentric lamellæ, the fibrous tissue of which gradually becomes merged into the endoneurium. In the endoneurium itself there is a marked increase, more particularly in some places where the individual nerve fibres are seen to be surrounded by a noticeable amount of new fibrous tissue. In longitudinal section the nerve fibres pursue an irregular undulating course and are separated by considerable amounts of fibrous tissue. These changes are more marked in the smaller of the two portions of nerve connected with the tumour.

The tumour is what is described as a "false neuroma"—i.e., a fibroma—arising in the course of a medullated nerve. The character and arrangement of the cells with the presence of so many thin-walled vessels are all, however, very suggestive of sarcoma.

Remarks by Mr. MOYNIHAN.—This case is an admirable example of generalised neuro-fibromatosis. The condition usually known as molluscum fibrosum was associated with a growth, possibly sarcomatous in nature, springing from the vagus nerve or its sheath on the left side of the neck. The question as to whether the soft pendulous masses distributed apparently at random over the whole body are soft fibromata originating in connexion with the sheaths of the peripheral nerves as held by Recklinghausen, or whether they are formed around the glands and hair follicles as suggested by Payne, cannot be considered as settled, though the balance of evidence is heavily weighted in favour of the former view.

The points of especial interest in this case are as follows: 1. The remarkable family history. The hereditary and inherited character of the disease is clearly apparent. 2. The general distribution of the soft, fibrous, more or less pendulous, nodules, and the brown pigmented areas, giving rise to the condition known as molluscum fibrosum. 3. The association with these of a localised tumour originating in connexion with the vagus nerve. The character of the tumour is probably that of the "secondary malignant neuroma" of Garré, of which the essential features are rapid growth, lack of infiltration except after recurrence, and absence of secondary deposits except in the latest stages. 4. The absence of any untoward effect after removal of a large portion of one vagus nerve.

A GENEROUS GIFT.—The town of Moreton Hampstead has been presented by the Hon. F. D. Smith, M.P., with a completely furnished hospital at a cost of £5000.

PAUPER FUNERALS.—At the meeting of the Swansea Board of Guardians held on Dec. 21st the undertaker to the union was censured for his action in taking the bodies of two paupers to the burial-ground in a grocer's cart and afterwards reading the burial service himself. The man admitted that he had followed this procedure in eight cases.

Medical Societies.

EPIDEMIOLOGICAL SOCIETY OF LONDON.

Plague.

A MEETING of this society was held on Dec. 14th, 1900, Dr. PATRICK MANSON, C.M.G., F.R.S., the President, being in the chair.

Dr. A. K. CHALMERS, medical officer of health of Glasgow, read a paper on the Plague in Britain in the Nineteenth Century. After shortly recounting the history of plague in Europe from the fourteenth century to the Malta epidemic of 1813 Dr. Chalmers passed on to consider the recent epidemic in Glasgow. He remarked that the origin of the outbreak was absolutely unknown. The first man attacked was a docker but employed on coasting vessels only, and he contracted it from his wife who sickened simultaneously with the infant whom she carried with her when hawking fish in the streets. Where they met the infection would never be known. Besides the cases traceable directly or indirectly to these and to the wakes were several of interest from their circumstances—a shoemaker and a man living on the other side of the river, neither of whom had to their knowledge had any communication with the infected family, though the one resided and the other visited at the adjoining houses. Then four cases occurred on Sept. 13th and 14th in a house where a person had died on August 28th from "pneumonia" (*sic*) with enlarged cervical glands. They were a man and his wife who had slept in a bed on which a previous case had died and which was presented to them by the friends of the deceased, and another case occurred in the same house. Some others who assisted with persons who had been present at the "wakes" might be looked on as cases of indirect infection. The origin of two cases at Govan on the other side of the river could not be explained. Special interest, however, attached to the case of the wife of a man employed in removing clothing from an infected house for further purification. So soon as a room was vacated its contents were exposed *in situ* for several hours to the vapours of liquefied sulphur dioxide and the floors, walls, &c., sprayed with formalin or chlorine. Clothing and bedding were then wrapped in sheets wetted with formalin and conveyed to the steam oven. The men employed in this work had all received immunising doses of Yersin's serum and none of them suffered. But the wife of one who lived at a distance from the infected district and had had no communication with contacts other than her husband was attacked and developed inguinal buboes, the most probable explanation being that he carried the infection in his hair, since they wore overalls at their work. Including fatal "pneumonias," &c., preceding recognised plague cases in the same houses, the attacks in the consecutive weeks ending August 4th to Sept. 22nd were 2, 0, 4, 10, 9 (2 at Govan), 2, 5, and 2, besides 2 in the hospital staff, the deaths in the respective weeks having been 2, 0, 2, 5, 3, 1, 2, and 1; in all, 36 cases with 16 deaths. With regard to the conditions of infectivity, the association of plague with gross insanitary conditions had never been questioned, but Dr. Chalmers was convinced that the susceptibility of the individual was greatly determined by the conditions amid which he lived. In Bombay those dustmen only whose homes were insanitary contracted the infection in the course of their work, and he believed that, as with typhus fever, the danger of infection in the wards of a well-conducted hospital was very small. In the Glasgow epidemic the virulence of the disease in the several foci was proportioned to their sanitary conditions and in the first centre further intensified by the overcrowding during the wake. The mortality among those who passed their incubation and sickened in their dirty homes was far higher than that of the contacts who were early removed to the purer air of the reception house, and in one house where 16 days elapsed between the first and the three secondary cases, two of which were mixed or septic infections, he was strongly inclined to believe that the bacilli had acquired increased virulence during a period of saprophytic existence in the filth of the tenement, every member of this family being attacked, while the 15 other families in the same house escaped. Professor Zabolotny of St. Petersburg, who was in Glasgow at the time, was much struck with the prolonged duration of many of the cases and the general mildness of the disease as compared with what he had observed in China and India and in the recent outbreaks at Kolubowka and Oporto. Indeed, if some of the cases that could not be accounted for were really due to direct infection the intervening terms of the series must have been so extremely mild as to have escaped recognition. In all 26 cases were admitted into the hospital and two occurred there. Eight of these died, giving a mortality of 28 per cent., approximately the same as in other recent outbreaks. In Smyrna it was 40 per cent., in Sydney 30, in Alexandria 48, and at Oporto among cases not treated with serum 63·7. But if the eight deaths occurring at home and not clearly recognised were included the death-rate at Glasgow would be really 44·4 per cent. Dr. Rosenau of Washington had shown that the bacilli of plague retained their virulence for 48 days in pieces of fabrics kept in the dark at a temperature as low as from 20° to 23° C., and if they could do the same or maintain a saprophytic existence in the hold of ships the introduction of the disease in the absence of known cases might be explained. The trade of Glasgow was largely carried on by vessels not plying directly with India or China but calling at various ports *en route*. At Glasgow no infection of rats was observed, for though they were plentiful in the district at the commencement of the outbreak they decamped so soon as disinfection of the drains and houses was begun. Nor were any of the rats obtained from vessels arriving from the East Indies, China, or elsewhere found to afford evidence of infection. There was no doubt as to the part played by these animals in the dissemination of the plague in India and China, but the species of rats differed in different continents and climates and so might their susceptibility. It might be merely a coincidence, but the old black rat of this country disappeared before the irruption of the brown one about the same time that the plague died out, and no conclusions could be drawn from the silence of Boghurst on the subject, his statement as to foxes and serpents dying from the plague being obviously the mere repetition of a tradition and not the personal observation of a London apothecary. In his extremely curious and interesting "Loimographia," which after having existed for 230 years in MS.[1] was transcribed and edited by Dr. J F. Payne and printed at the cost of the Epidemiological Society in their Transactions for 1893-94, Boghurst expressed himself somewhat inconsistently as to the essential nature of the plague, but insisted strongly on the importance of insanitary surroundings, filth, and neglect of personal hygiene as predisposing and favouring conditions, "furthering occasions" as he called them, an opinion in which all were now agreed.

Dr. J. F. PAYNE said that there were records of the prevalence of the plague in Bombay in the seventeenth century and of its subsequent disappearance as in Europe. When it reappeared in any country it always did so in several places simultaneously, spreading by ordinary infection and recurring at intervals as it were *de novo*, as Pepys graphically described its progress from west to east in London during the year 1664–65, slower than if it had been carried by ordinary contagion. The expression "soil" as used by the writers of that time did not mean the earth only but included every extra human condition or factor. The existence of the bacillus as a saprophyte was undoubted and, as he had said in Allbutt's System of Medicine, it need not be feared in a really sanitary city.

Dr. F. TIDSWELL of Sydney remarked on the contrast between the large element of personal contagion observed in Glasgow and the evident activity of the rats in Sydney. The first case there was a man who had never been away but was carrier to a shipping firm. The rats died by thousands, and six of 15 caught on one wharf yielded plague bacilli, as proved by cultures and inoculations. The next 50 or 60 cases were men of every class, from clerks to labourers, employed in or about the same wharf. A family at a considerable distance were next attacked, but they frequented a dust-tip where refuse from the wharf was thrown. Then some cases occurred quite independently in some suburban houses of a good class, but plague rats were found in each. Save among the occupants of the same house direct contagion was never observed, unless the cases of a young man who stood for some hours in a crowd at the send-off of the Australian contingent and of a young woman superintending a stall at a bazaar were instances. There were very few secondary cases, plural

[1] British Museum, Sloane MS., 349.

attacks being either simultaneous or at intervals too long for connexion, and but one or two per 1000 of the scavengers contracted the disease. As to the rats, the only question could be whether the infection was conveyed by them to man or they contracted it from him. In every place the rats were attacked first and their dead bodies found before an outbreak, but he believed that fleas acted as intermediaries and vehicles, for though he had failed to infect animals by their means under natural conditions he had done so by inoculating an emulsion of such fleas and had found the bacilli in their bodies. As to types, most of his cases were bubonic, a few were septic, and two were pneumonic. Since, however, bubonic cases might take on these more dangerous characters he thought that by the early isolation of all cases the virulence of an epidemic might be lessened.

Dr. E. WILLOUGHBY wished to know whether the so-called "Australian" rats were specifically identical with Europe or of India and China, since there were none, indeed no mammals, indigenous to the country. It might be that as with the anopheles and the culices, the one was a source of danger and the other harmless in this respect.

The PRESIDENT said that he believed in rats but he believed also in fleas; there were, however, many species of rat and one, the musk rat, was stated to be immune. The Chinese illogically held a dead plague rat to be protective against infection, and he had recently been told of a thrifty native Christian and his guests being attacked after dining off rats that had died from the plague.

LIVERPOOL MEDICAL INSTITUTION.

Epidemic Arsenical Neuritis.

THE sixth ordinary meeting of this institution was held on Dec. 20th, Mr. EDGAR BROWNE, the President, being in the chair.

Dr. NATHAN RAW opened the discussion on Epidemic Arsenical Neuritis, remarking that during the last 12 months he had had 148 cases of neuritis under his care, most of them presenting the appearances of alcoholic neuritis. During the last month the symptoms were different, being more those of acute irritant poisoning than of chronic neuritis. He was of opinion that the first serious contamination of beer with arsenic took place about May last and a sudden contamination about the middle of November. He had found arsenic in the urine in five cases, all recent admissions, and although he had carefully examined 31 other cases no trace of arsenic could be found. He was of opinion that arsenic had a different action in the presence of alcohol.

Dr. ERNEST S. REYNOLDS (Manchester) gave a short account of the steps which led to the theory, and afterwards to the proof, that arsenic present in certain beers was the cause of the epidemic. He mentioned some symptoms not previously noted and stated that any treatment pursued should take account of the great heart weakness present. He finally referred to the possibility of arsenio-bacteria being present in the beer and having something to do with the carriage of the arsenic.

Mr. G. S. STANSFIELD (Birkenhead) stated that usually he had, as medical officer of the Birkenhead Union Workhouse, three or four cases of peripheral neuritis in the year, whereas recently there had been 32 cases, the increase beginning in October. The average time from first symptoms to admission was 11 weeks, the average age was 45 years, and although some were spirit-drinkers as well, yet all were beer-drinkers, on an average of three pints of beer per diem at 6*d*. per quart. The symptoms common to all were numbness in the hands and feet, pricking like pins or needles or "nettles," cutaneous and muscular hyperæsthesia, loss of knee-jerk, and ataxia. Pigmentation was, except in one case, so slight as to be overlooked, but it was present in one-third of the cases. Several patients had cardiac dilatation and bronchitis; severe sweating was seen in others and also desquamation. The beer used by several patients had been found to be free from arsenic, hence he would say (1) that there was an epidemic of peripheral neuritis; (2) that some of the cases had symptoms of arsenical poisoning; and (3) that the administration of arsenic in beer seemed to be more potent, since many patients had but one pint of beer per diem, the disease in one such case ending fatally.

Dr. R. J. M. BUCHANAN considered that this epidemic of peripheral neuritis conveyed a lesson emphasising the necessity of members of the medical profession individually to cultivate the faculties of observation and deduction to the highest degree; that the familiar association of alcohol and peripheral neuritis in relation to cause and effect had no doubt tended towards a want of credulity regarding the statements made by patients who denied excess, thus narrowing the field of mental vision and hindering the elucidation of the truth. Noticing the increase in number since July of patients at the Liverpool Stanley Hospital on his days of attendance with obscure nerve-pains and peripheral neuritis, cross-examination in reference to alcohol as a cause did not elicit excess or a history of spirit-drinking as a response The possibility of lead in beer was considered, but the special symptoms did not support the suspicion. The cases which had come under his notice exhibited several points of interest. 1. The history of beer-drinking in moderation only, in some cases not more than one and a half glasses per diem. 2. The peculiar alteration in the first sound of the heart, which approached the second in character, rendering the heart sounds "fœtal"; the small frequent pulse. 3. The hyperæsthesia and hyperalgesia of the lower extremities, particularly the feet, with anæsthesia of the fingers; the sweating of the hands and feet. In one patient the anæsthesia of the hands commenced in the thumb and gradually attacked each finger in sequence, the little finger last. In holding a cup by the handle the patient did not recognise that she held it safely until pain was felt in the fingers by the excessive pressure which she had to exercise. As a cigarette-maker her work was interfered with, not only by the anæsthesia of the fingers interfering with delicacy of touch and paresis with movement, but particularly by the production of pain. Paræsthesia was present in nearly all cases as a sensation of "prickling" or "pins and needles"; one man complained that he felt as if he were walking with his "bare feet upon ice"; another as if he had "a round ball under the sole of each foot," upon which he was always trying to balance himself to lessen the pain. 4. The absence of any very marked loss of power (except in extreme cases), ataxia, or mental symptoms. 5. The association of œdema in some cases and not in others. 6. The peculiarity of the pigmentation, its varied intensity, and its distribution, fading towards parts most exposed to the air or subject to the least pressure. 7. The dryness and desquamation of the skin of the trunk, in some cases branny in character, in others exfoliating in flakes, the flakes of epidermis being white, indicating a deposit of pigment in the deeper layers of the cutis. The peculiar condition of the nails, which were occasionally raised up and loose; in one case the nails on the fingers presented a well-marked transverse ridge, indicating the approximate date of the initial trophic disturbance. 8. The occurrence of skin eruptions; in two cases intercostal herpes zoster, in another herpes of the buttock and extending to the knee; in one case a patch of erythema on the back nine inches square, with dermographia; in one case large patches of urticaria were present all over the body, with the exception of the hands, feet, and scalp; these were raised above the skin level from one-sixth of an inch to three-eighths of an inch and varied in size from one inch to eight inches in the greatest diameter. 9. In one case, that of a woman in whom the general symptoms were pronounced, there were both laryngitis and bronchitis present, also a rapid enlargement of a previously small and quiescent goitre. 10. In only one instance was Dr. Buchanan successful in detecting arsenic in the urine to his satisfaction. The case was a severe one under the care of Mr. H. W. Nott of Little Sutton. No difficulty was found in obtaining characteristic reaction by Reinsch's method, and subsequent sublimation from six ounces of distilled water to which had been added a quarter of a drop of liquor arsenicalis, B.P. The rapid enlargement of the thyroid gland which occurred in one of the cases suggested the possibility that the peculiar condition of the skin, the falling hair, and the pigmentation might be due to the arsenic in a direct or indirect way affecting the thyroid gland and perhaps the suprarenal glands. Relative to this suggestion Dr. Buchanan offered the following points for consideration. (*a*) At a meeting of the institution held on Oct. 17th, 1895, in the discussion which followed an admirable paper on Exophthalmic Goitre by Dr. J. H. Abram, Dr. Buchanan related a case in which, during a quiescent period of the disease, the exhibition of liquor arsenicalis in doses of three minims three times a day, with the hope of diminishing the anæmia, was followed within 48 hours by great prostration with inability of the patient to stand alone

and an aggravation of all symptoms. The drug was immediately withheld. 11 weeks later it was again tried with a similar, but not so severe, result. Several recorded cases in the *Manchester Medical Chronicle* pointed to the aggravation of the symptoms on administering arsenic. More recently arsenic had been suggested and used with variable result, in conjunction with the administration of thyroid gland, to prevent symptoms of thyroidism. Although these observations seemed diametrically opposite they tended, at least, to show that arsenic, in a manner the *rationale* of which is not fully known, might probably exercise an influence on the thyroid gland. (*b*) The close association of pigmentation, localised or diffuse, in patients suffering from "Graves's disease." (*c*) The association of pigmentation with latent thyroidism. (*d*) The pigmentation of gestation, during which period the thyroid gland was enlarged and more active. (*e*) The characters of the skin in myxœdema and hypothyroidism. (*f*) The increased frequency of the pulse and tremor in arsenical poisoning and Graves's disease. (*g*) The number of cases of arsenical poisoning had been greater and the symptoms more pronounced in women (in whom affections of the thyroid gland were more common than in men). (*h*) The presence of iodine as a normal constituent of the thyroid gland; the prevention of pigmentation during the administration of arsenic by the use of iodine at the same time. Referring to the presence of arsenic in beer Dr. Buchanan drew attention to the possibility of contamination occurring in the following ways. 1. The use of sulphuric acid containing arsenic as an impurity in the "converters" in the manufacture of glucose, or at a later stage if used as a bleaching agent in the "vacuum pan." The same might apply to the inversion of Jaggery sugar. 2. Bisulphite of lime containing arsenic as an impurity, if used for the washing out of brewing vats or "cleaning casks," or washing the beer barrels after "steaming," or as a "fining." 3. The use of sulphuric acid to cut the isinglass in the preparation of "finings." 4. The possible contamination of grain by the use of artificial manures containing arsenic. In the manufacture of glucose lime was used to neutralise the sulphuric acid in the liquor from the "converter"; after neutralisation it was passed through press-bag filters and the residue was used as manure. 5. The possible contamination of hops if bleached by the use of bar sulphur. 6. Contamination of the malt by the use of anthracite coal in the kiln or by sulphur. Dr. Buchanan drew attention to the use of lime for cleansing purposes and the possible combination with it of lactic and malic acids in the beer. Decomposition of these substances if brought about by the action of certain organisms would result in the evolution of nascent hydrogen which, combined with the arsenic to form arseniuretted hydrogen, one of the most poisonous forms of arsenic. If lime and soda were used for cleansing barrels, &c., a combination of arsenic and soda might take place and produce an easily absorbable compound. If so it might account for cases in which the symptoms were sudden and severe, especially as beer was so often taken on an empty stomach, facilitating rapid absorption. The production of arseniuretted hydrogen in a somewhat similar manner had been shown to occur and had been put forward as a means of poisoning from arsenical wall-papers. Dr. Buchanan exhibited a series of plans illustrating the construction of a complete maize milling plant for manufacturing pure degermed meal, maize oil, and cake; also of plant and machinery for the manufacture of white liquid glucose with a capacity of 70 tons per day. A concise description of the process of manufacture and a "key" to the plans were also provided.

Dr. F. H. BARENDT divided the eruptions present in arsenical neuritis into two classes: (1) after heavy drinking, and (2) after moderate drinking. Under the first class erythromelalgia, erythema of the face, urticaria, and hyperidrosis were observed. Under the second class zona, palmar and plantar keratosis, and pigmentation were observed. The diagnostic differences between arsenical pigmentation and Addison's disease were fully described. The pigmentation in these cases, which had been noted by writers on drug eruptions, was physiological and not due to any deposit of arsenic in the skin, in contrast to argyria, where the presence of the silver had been detected in the tissues. It had been overlooked or mistaken for morbus Addisonii and phtheiriasis.

Dr. GLYNN had met with cases of arsenical neuritis with the pigmentation and eruptions described by the previous speakers and would not refer to them. He had seen a woman who after a few glasses of beer was attacked with neuritis; the affection commenced with sore-throat, diarrhœa, and general œdema early in October, and although no beer had been taken since the onset of the disorder the symptoms of neuritis had up to the present time become aggravated. The amount of arsenic in the beer consumed was about one-seventh of a grain to a pint. She had taken iodide of potassium from the first without benefit; from his experience in this and other cases he concluded that this drug was of no value in arsenical neuritis. He was not prepared to accept Dr. Reynolds's theory that alcoholic neuritis was invariably due to arsenical beer, as he believed that he had met with the disease in women who were spirit-drinkers and took no beer.

Dr. W. CARTER thought that some startling revelation of this kind would alone rouse the country to the dangers and anomalies of the public traffic in alcohol. In 1837 when it was found that there were 6·5 deaths per 1,000,000 of the population from arsenic a popular clamour was excited, issuing in an Act of Parliament which fenced its sale with restrictions, the effect being that in 1897 the mortality had fallen to 4 per 1,000,000 in a population of 30,000,000. In the years 1876 to 1880 the Registrar-General's returns showed an annual mortality from the *direct* effect of alcohol of 38·4 per 1,000 000, but no alarm being felt and no Act being obtained for restricting the sale of this poison it had risen in 1897 to 77 per 1,000,000. Dr. Tattersall had published returns which showed an extraordinary decline in the death-rate of Salford owing, as he believed, to the abstinence from beer-drinking during the last week or two in that town. The present scare would soon die away and adulteration probably be again practised unless some method of permanently securing the public interests was enforced. If men would not abstain altogether they should at least have a drink free from poison, and much good could be done by medical men as well as by others by supporting the recommendation of the Brewers' Commission as to the necessity of analyses. But these analyses should be periodical—say, quarterly; they should be made at the brewers' expense and should be accompanied by a certificate of purity which the licensee of the public-houses should be bound to expose in a conspicuous place so that everyone entering the house might see it; or Sir Cuthbert Quilter's Pure Beer Bill should be passed. Such glaring anomalies as prevented the holders of the railway stock of the London and North-Western or Midland Railway from sitting as justices on a licensing bench because of the infinitely small interest they had in the companies' hotels, while permitting the directors or chairmen of companies of glucose manufacturers that supplied brewers all over the Kingdom and had a direct interest in promoting the sale of beer, ought to be abolished. As for the traces of arsenic that could get into barley from soil or into beer from bacteria they might be disregarded. What was wanted was a periodical analysis by competent chemists that would insure the public against injurious additions, whencesoever they might come.

Dr. E. W. HOPE, in referring to the administrative aspects of the question, said that as soon as the cause of the neuritis was suspected it appeared to him that the first and obvious duty was to remove all arsenical beer from the possibilities of consumption. The first step was to ascertain which of the brews were likely to be poisoned and where the contaminated beer was being sold. The solicitor to the Brewers' Association was requested to call a meeting of the association forthwith, and in the meantime samples of beer were purchased in various parts of the city for a qualitative analysis, only to determine whether or not arsenic was present, irrespectively of quantity. The brewers placed themselves unreservedly in the hands of the health department and decided to destroy any beer which might reasonably be suspected of contamination. The Food and Drugs Act, on account of its slowness of action and from the fact that proceedings would lie against the retailer or licensee of the public-house and not against the brewer, was not considered a good weapon to cope with the poisoning. The Public Health Act, by which the medical officer of health or his representative was empowered to seize any article of food which was unfit for consumption and which was exposed or deposited for sale, was the weapon actually put into force. Before this Act could be put into force it would be necessary to have reasonable grounds for the belief that each barrel seized contained arsenic. So far as the brewers were concerned the poisoning

was accidental and no guilty knowledge could be proved against the retailers as would be required by the Food and Drugs Act. Quantities of beer were turned into the sewers, being seized as the result of the analyses which came to hand. The official records showed that 181,000 gallons were destroyed in Liverpool alone, besides large quantities of which there was no official record. As regards the results of analyses, no arsenic was reported in any samples taken in the ordinary way during October, and when the specific search was made for arsenic the quantities per gallon varied widely, from one and a half grains per gallon to a trace, one-fifth of a grain. Sugar was accountable for the worst class; accidental contamination might explain the other, and one not improbable explanation of this class was that the holds of vessels used for the carriage of pyrites in bulk had subsequently been used for the transport of grain in bulk. The use of flats and lighters in a similar way might also suggest a similar source of contamination. Alcoholic poisoning in Liverpool was very common, inquests being held upon scores of men and women whose deaths were ascribed by the juries to alcoholic poisoning. So usual was this that no one remarked it, but the accidental addition of a new poisonous ingredient, to which perhaps half a dozen deaths had been partially due, aroused attention. He suggested the appointment of a committee to consider what steps could be taken to prevent the recurrence of such an incident.

Dr. LESLIE ROBERTS said that the cutaneous symptoms in the present epidemic could be conveniently arranged into two natural groups—viz., (1) the chronic vaso-motor group and (2) the nutritive group. The former group included the phenomena of cyanosis, paresis of the peripheral vessels, especially well seen in the face and the main furrows of the palms, and the fixed erythemata of the palms and soles. This type of erythema, called "erythromelalgia," was associated with pronounced hyperidrosis and usually with distinct evidence of sensory and motor neuritis. It constituted the "pink palm" of a past generation. The nutritive changes were (1) pigmentation, (2) exfoliation, and (3) keratosis. The pigmentation was a physiological melanoderma. The exfoliation was comparable to that which takes place in the case of a frog poisoned with arsenic—viz., the separation of the horny cuticle from the underlying epithelium. The effects of arsenic were marked in the palms, which acquired an aspect like wet shagreen; the furrows were coarse and exaggerated and presented a brownish-red colour. To the touch the palm felt uneven and lumpy from the presence of solid nodules with a shining, flat-topped aspect. In cases where hyperidrosis and nerve symptoms were less marked the palms showed signs of black keratosis in circular patches, tending to fuse into larger patches. The nails were usually affected, the matrix being thickened and the nail discoloured.

Dr. W. A. NEWALL (Chester) remarked upon the sudden incidence of the cases in Chester, from one or two during eight months to 15 in two weeks. The rapid onset of the symptoms and their great similarity—viz., pain in the feet, numbness of the feet, legs, and hands, acute tenderness of the calf muscles, rapid severe paralysis of the legs followed by atrophy, œdema of various degrees, and dilatation and irritability of the heart—these symptoms occurring absolutely alone in the first 20 or 25 cases. Dr. Newall wished to know if it were possible to have a condition of arsenical intoxication of such severity as to cause severe and rapid paralysis and very marked sensory phenomena without vomiting, diarrhœa, colic, inflammatory skin-lesions, pigmentation, or tremor? If this were possible the cases occurring in Chester might be due to arsenical poisoning; if not, that poison could not be the cause.

Dr. PRYTHERCH claimed that there was strong evidence of the epidemic in Chester being one of beri-beri, and said that he was supported in this view by Major Ronald Ross, I.M.S., who had seen these cases. If these cases were due to arsenical poisoning it was but fair to infer that the severity of the symptoms should have some relation to the amount of beer consumed. He did not find such relation, even total abstainers being affected. It had been stated that traces of arsenic had been found in but 14 per cent. of even acute cases. That did not warrant the conclusion that the epidemic was due to arsenic, nor did it follow that the finding of arsenic in urine was a proof of arsenical poisoning. Œdema, which was a constant feature of beri-beri, was present in all cases, and until the present epidemic this was not recognised as a symptom of arsenical poisoning. The same remark applied to the peculiar spacing of the heart-sounds. He quoted cases from his own experience which had been treated with large doses of arsenic, in some of which the patients had recovered and in the others they were improving; their beer was not stopped. He did not think that arsenic in the beer was the sole cause of the epidemic, but that there must be some other more potent cause, and this when discovered might explain the etiology of beri-beri.

Dr. J. ERNEST NEVINS commented upon the amount of freckling found in these cases of arsenical neuritis. Amongst 14 cases in one ward under his care there were eight patients with freckles with or without other pigment, whilst in the next ward amongst 14 non-neurotic patients of similar ages and social conditions there were only four with freckles. The cases in the Liverpool parish hospital were fewer and of a milder type than were those at West Derby Hospital.

Dr. J. H. ABRAM said that the majority of the cases he had seen did not present any pigmentation. The paresis also was but slight, the inability to walk being due to excessive tenderness of the skin of the feet. The absence of characteristic skin lesions made the examination of the urine imperative, but owing to the rapid elimination by the kidney it was necessary to apply the tests as soon as the case came under notice. He thought that this might explain the failure to detect arsenic in the urine in some cases.

Dr. D. SMART stated that although he was a medical officer of a workhouse he was in the position of having had no arsenical cases under his care. He took it that the gastric symptoms, the eye lesion, and the pigmentation were the things to be looked for in arsenical neuritis, and although his cases had been seen by other physicians no one had found anything definite pointing to the arsenical origin in the seven cases of neuritis which he had under his care at Smithdown-road Workhouse.

Major ROSS, I.M.S., also spoke, and Dr. RAW and Dr. REYNOLDS replied.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF SURGERY.

Nephrectomy.—Radical Cure of Femoral Hernia.

A MEETING of this section was held on Nov. 9th, 1900, Mr. THOMAS MYLES, the President, being in the chair.

Mr. FRANCIS HEUSTON brought forward a case of Nephrectomy for Sarcomatous Tumour of the Kidney. The patient was a woman, aged 24 years, who noticed a small painless swelling in her right side in the winter of 1898. In February, 1899, she had a severe attack of hæmaturia, lasting for three days, which then ceased and did not recur. From that time the tumour gradually increased in size, and in September its weight gave rise to a dragging pain in the side when she was in a vertical position. When seen by Mr. Heuston a large tumour occupied the right lumbar and umbilical regions, extending to the linea alba; above it passed beneath the costal arch and below to the level of the superior iliac spine. It was not attached to the skin and it moved freely within the abdominal cavity; it felt smooth, was of stony hardness, and had well-defined edges. Examination did not give rise to pain or tenderness. On Feb. 1st, 1900, the usual oblique incision for lumbar nephrectomy was made and the tumour was exposed, when it was evident that the growth was chiefly cystic. Some of the larger cysts were tapped by an aspirator needle, removing a clear watery fluid containing albumin but not urea. The pelvis of the kidney was greatly enlarged and was occupied by a firm growth which extended down the ureter to the position where it passed into the true pelvis over the iliac vessels. Here the thickening ceased abruptly, leaving an apparently normal ureter below this point. This was ligatured and the affected portion was dissected upwards to the kidney, separating the pelvis from the renal vessels, which were then ligatured; the whole tumour was then removed without difficulty, the peritoneal cavity not being opened into. The patient's recovery was rapid and uneventful, the only point of interest being an immediate increase in the amount of urine, which now averaged 40 ounces in 24 hours, as compared with 21 ounces before operation. The kidney weighed 20 ounces after it had been bisected and most of the fluid drained away. An increase in the quantity of urine was a well-known phenomenon after operation in cases where one kidney was diseased and functionally inactive for a long time and the

other kidney, being in a healthy condition, had had to do all the work. Whether that was due to the source of irritation being removed or to nervous reflex action had not yet, as far as he knew, been decided.

Mr. H. GRAY CROLY communicated a series of cases in which he performed the Radical Cure of Femoral Hernia by the displacement method originally introduced by Kocher of Berne.

BRITISH BALNEOLOGICAL AND CLIMATOLOGICAL SOCIETY.—A meeting of this society was held on Dec. 14th, Dr. Symes Thompson in the chair in the absence of the President.—A paper on the Suppression of Malaria was read by Dr. Arthur Waddell. After traversing the etiology of the disease and the different methods for its mitigation and suppression he concluded by saying that "methylene blue and non-poisonous larvicides, a minute hydraulic survey of each district followed by the pumping engine, the covered drain, and the protected water area, are the hosts upon which we must rely to lead us to victory." After speaking of segregation and the practicability of the measures inculcated he concluded as follows: "Of the positive effect of the measures considered, where they can be intelligently applied, there can be no doubt. The only question remaining is that of economics. If a jury of business men were empanelled to adjudicate on this point the first question they would ask would be, 'Will it pay?' and the answer would come back triumphantly, 'Yes, pay many times over.' For the healthy energy of a country is the true index of its wealth and greatness, and where malaria is, are diminished health and subdued energy. But what, I ask, has the question of pounds and liras and lacs of rupees got to do with malaria suppression when the cause of humanity demands it? If a man's health, life, and happiness be placed in one scale of the balance against all the gold of the universe, the diamonds and precious stones of the mine, and the pearls of the sea, will it not weigh them all down? Economics must nevertheless have a certain say, for we must be just as well as generous. Nations must rise to their duty to the best of their ability and be ready to make big sacrifices in the good cause. Many things of the luxurious order can be dispensed with, one, not the least, some portion of the betinselled and hysterical militarism which absorbs so many energies. Ross's discovery has come as a fitting crown to a century already glorious in its ending. Let us hope that the new century will master the problem which is thus unfolded and that in rising to grapple with it our beneficent British empire, great in the ownership of malarial territory as she is in many virtues, must lead the van."—Letters of regret at unavoidable absence were read, amongst others, from Surgeon-General H. S. Muir, Colonel Johnston and Major W. G. Macpherson of the Army Medical Service, Professor McLeod of Netley, Major R. Ross, I.M.S., Dr. H. E. Annett of Liverpool, &c. Major Ross in a letter to the lecturer said: "My view on prevention of malaria is that our principal malarious towns should be kept as well drained as possible and that municipalities should keep mosquito-killers; also that Governments should issue instructions to their sanitary officials to take steps in these directions." Dr. Annett, a member of the Liverpool malaria expedition, wired: "Cannot too strongly urge segregation of Europeans and efficient surface drainage as only measures against malaria in West Africa. Quinine, mosquito-proof houses, &c., absolutely impracticable."—An interesting discussion followed the reading of the paper in which the chairman, Surgeon-Major Black, Dr. Fortescue Fox and Mr. Tregelles Fox (Strathpeffer), Dr. L. J. Hobson (Harrogate), Dr. Morgan Dockrell, and others took part.—Mr. Ernest E. Austen of the British Museum and a member of the Liverpool West African expedition, in alluding to some of his experiences expressed the fear that in Sierra Leone, at all events, there could not be much hope of inducing the negro population to act up to the standard, fearing that there was no possibility of educating them sufficiently on the subject.—Dr. R. W. Felkin showed a Mosquito Net which he, Gordon Pasha, and Emin Pasha had used in 1878.—Dr. Waddell, in reply, expressed confidence in the civilising force of educated control against any native inertia where caste was not concerned, and in reply to Mr. Tregelles Fox's query as to where the special parasite had been in the ages pointed out the enormous duration of man in the world, amounting probably to a quarter of a million of years, and that the origin of the human forms of the sporozoa was to be found in the ordinary process of specialisation through evolution.

WINDSOR AND DISTRICT MEDICAL SOCIETY.—The third meeting of the session of this society was held at the Guildhall, Windsor, on Dec. 19th, Mr. W. B. Holderness, the President, being in the chair.—Dr. E. B. Hulbert showed (by kind permission of Mr. J. R. Lunn of St. Marylebone Infirmary) the following:—1. A Heart affected with Ulcerative Endocarditis. 2 Drawings and Photographs of Uncommon Diseases, including myxœdema, cretinism, cancer of the male breast in a patient aged 91 years, foreign body in the female bladder, anæsthesia following herpes zoster, sebaceous cyst of the buttock, malignant disease of the tongue, hare-lip, goitre, &c.—Mr. Arnold Thomson showed a case of well-marked Mitral Regurgitation in a man who had never had any illness and considered himself strong and well.—Dr. H. B. Milsome showed a patient with Narrowing of the Left Palpebral Cleft and Dilatation of the Left Pupil. There was a swelling in the neck which it was suggested was pressing on the cervical sympathetic.—The President showed a patient who was able to demonstrate a Perforated Membrana Tympani by passing air very audibly by Valsalva's method.—Dr. G. E. Hale showed: (1) A case of Chronic Epididymitis associated with Hydrocele; and (2) a patient with a Fibroma of the Arm causing anæsthesia of the fingers by pressure on the median nerve.—Dr. G. Leslie Eastes read a paper on the Histology of the Urinary Tract in Relationship to Morbid Urinary Deposits, giving a lucid description of the epithelial lining of the urinary tract from the cortex of the kidney to the meatus urinarius. Illustrations carefully drawn to scale were exhibited, showing the various appearances presented by the cells in microscopical preparations of urine.—Dr. E. S. Norris introduced a discussion on the question as to whether excessive athletic exercises in the young were productive of any ulterior bad effects. After quoting some statistics from the late Dr. Morgan's book, "University Oars," which certainly did not appear to show that rowing tended to shorten life, he gave personal testimony to the hard work entailed by boat-racing. In the course of his experience, however, he had only seen one case in which it appeared to him that ill-effects had certainly followed, but it was, he admitted, no uncommon thing for other physicians to see these young oarsmen and curtail their athletic exercises and prescribe a course of treatment for dilatation of the heart.—The discussion was continued by Dr. W. A. Ellison who said that he had systematically examined the boys rowing in the Eton crews for the last eight or nine years and to a certain extent for the last 16 years. After pointing out that most of the cases where ill-effects were supposed to have ensued as a result of the university boat-race broke down on a closer examination, he expressed the opinion that provided a young man had a perfectly sound heart and was otherwise in good health boat-racing with training would do him no harm, but if he were out of sorts or in any way in bad health it would do him an injury. He further pointed out that the heart of a young man who had indulged in boat-racing showed some hypertrophy which was in his opinion quite a normal and salutary result.—On the motion of the President the discussion was adjourned till the next meeting.

MIDLAND MEDICAL SOCIETY.—The third ordinary meeting of this society was held on Dec. 12th at the Birmingham Medical Institute, Mr. Jordan Lloyd, the President, being in the chair.—Mr. H. G. Barling showed a male patient, aged 19 years, who received a Blow from a Railway Buffer on Sept. 20th, 1900. The shock was moderate and was followed by slight symptoms of peritonitis and by a steadily increasing accumulation of fluid in the abdomen, associated with jaundice, occasional vomiting, and at the end of a few days some diarrhœa, the stools containing a lot of bright green biliary colouring matter. The abdomen was opened at the lower part on the thirteenth day and about six pints of what appeared to be pure bile were collected, a large quantity in addition escaping; there was no trace of blood seen. The discharge from the incision ceased in three or four days and no further abdominal mischief ensued, but a left pleural effusion followed, and eventually about 70 ounces of bile-stained but not purulent fluid were removed by aspiration. Rupture of the gall-bladder was inferred, rather than rupture of the liver or ducts, because no hæmorrhage was found in the abdomen, which would pretty certainly have been the case had the liver been torn; further, it was difficult to see how rupture of the ducts should occur without injury to the liver substance.—Mr. Barling also showed a large single Gall-stone

removed from a woman who suffered from attacks of pain in the epigastrium and in the back but without vomiting or jaundice. The interest of the case lay in the fact that a moveable lump could be felt in the abdomen below the liver, the mobility being so free that the mass could be displaced downwards several inches. The explanation of this lay in the very much elongated gall-bladder, the distal end of which could be brought three inches out of the abdominal incision; it contained only the one stone.—Mr. Barling also showed the Liver, Bile-ducts, and Duodenum of a patient from whom he had removed a gall-stone impacted in the common duct close to the duodenal opening. Two operations were performed at an interval of one month. The patient did well for four days, when leaking from the duodenum began which was followed by rapid loss of strength, and the patient died on the seventh day after the second operation. The necropsy showed no general peritonitis, but a cavity contained material which had escaped from an opening in the duodenum about three-quarters of an inch in diameter.—Dr. O. J. Kauffmann showed two cases illustrating the results of Meningitis.—Dr. Douglas Stanley showed a patient, aged 52 years, who had marked Rhythmical Movements of the Right Arm and Leg. His occupation was that of sorting scrap iron. He had had no important illness and there was no history of syphilis. The movements had been present for two years, having begun in the right arm and then appearing in the right leg and foot. The diagnosis as to the case being a form of choreic affliction or one of paralysis agitans was discussed.—Mr. Smallwood Savage read a note on a case of Complete Rupture of the Uterus and Vagina successfully treated by drainage and suture.—Dr. W. Lamb read a paper on the Diagnosis of Nasal Obstruction.

GLASGOW OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.—A meeting of this society was held on Dec. 19th, 1900, Dr. Robert Jardine, the President, being in the chair.—Dr. A. W. Russell showed a Fœtus with Hydrocephalus and Spina Bifida. He also read notes regarding the Dilatation of the Cervix and showed a set of dilators where the different sizes were more exactly graduated than was generally the case.—Dr. Bell Todd showed:—1. Two Calculi which had been passed by a patient who had some years previously suffered from renal colic. She was pregnant a few months at the time the calculi were passed. Abortion followed 10 days later. The pain was in the left groin and thigh, so presumably the calculi came from the left kidney. A point of interest was that after the second confinement the abortion was her third pregnancy, Dr. Todd diagnosed a left floating kidney. 2. A Large Calculus removed through the interior vaginal wall.—Dr. Munro Kerr read notes of a case of "Missed Abortion." The woman had amenorrhœa for about four and a half months. Then a little discharge began to escape from the vagina. This occurred at frequent intervals for four months, when she was sent to him by her medical attendant. A diagnosis of "missed abortion" was made. The uterus being dilated, the shrivelled-up fœtus, with placenta and membranes entire, was removed. The fœtus seemed to be of about the age of four months.—Dr. Balfour Marshall read notes of a case of Missed Abortion where there was prolonged amenorrhœa with the retention of the ovum for a period probably of 12 months, but undoubtedly for at least five months, until removed by operation. The woman suffered from attacks of pain in the lower part of the abdomen, as if the uterus was from time to time trying to expel its contents. Great rigidity of the cervix existed, so that incisions had to be made into it before the ovum could be removed. In Dr. Marshall's opinion that might have in part been the cause of the retention of the dead ovum.—The President also read notes of a case of "Missed Abortion." In this case the woman had a slight hæmorrhagic discharge when she was about five months pregnant. A few days' rest stopped the bleeding and she had no other symptoms until full time when labour pains came on spontaneously and a five months' fœtus was expelled. The placenta was adherent and had to be removed manually. The President discussed the question of interfering when the diagnosis of death of the fœtus was made, and gave it as his opinion that provided there was no disturbing symptom the case was best left alone and labour allowed to come on spontaneously.—From this opinion Dr. Kerr dissented and considered it most desirable to empty the uterus whenever the death of the fœtus was diagnosed with certainty.

CHELSEA CLINICAL SOCIETY.—A meeting of this society was held at the Jenner Institute of Preventive Medicine, Chelsea-embankment, on Dec. 18th, Dr. William Ewart, the President, being in the chair.—Dr. F. T. Hewlett read a paper on Malta Fever. After welcoming the society to the institute and paying a tribute to the memory of the late Surgeon-Captain Hughes Dr. Hewlett reviewed the main features of the disease. He remarked that Malta fever had now been met with in all parts of the world and it was not improbable that cases would be seen among the troops returning from South Africa. He drew attention to the undulant character of the temperature curve and to the nervous and arthritic symptoms. The pathology was next discussed and the micrococcus Melitensis was described. The differential diagnosis and the value of the agglutination test were mentioned and the treatment was indicated. The paper was illustrated by lantern slides, microscopical preparations, and cultures, the agglutination reaction being demonstrated.—A discussion followed in which the President, Dr. C. A. Morris, and two visitors, Mr. Green and Mr. Rowland, took part. As to the treatment of Malta fever the consensus of opinion tended towards the pursuing of a strengthening dietetic course. No specific was known that had the slightest effect on the course of the disease. Quinine in any quantity beyond tonic doses was, if anything, harmful, and so far all attempts at producing an anti-serum had been fruitless. In the course of his remarks Dr. Ewart referred to the connexion between certain rheumatoid symptoms and toxæmia resulting from dental and oral suppuration. The point arose in connexion with the quasi-rheumatic characteristic often presented by Malta fever and was an instructive one as illustrating the fallacy of regarding all joint pains of a rheumatic semblance as being symptomatic of true rheumatism.—A unanimous vote of thanks to Dr. Hewlett for his paper and for the hospitality accorded to the society at the Jenner Institute terminated the meeting.

GLASGOW SOUTHERN MEDICAL SOCIETY.—A meeting of this society was held on Dec. 27th, Dr. William Watson, the President, being in the chair.—The special committee appointed at a former meeting to consider the question of the abuse of hospitals and dispensaries laid their report before the society. After some discussion the following recommendation on the subject was approved:—

That in addition to any other method at present in existence or under consideration by the directors of such hospitals patients desiring treatment at the outdoor dispensaries should obtain a printed form containing a declaration that his or her circumstances are such as warrant gratuitous treatment; and that this form be signed by the patient and by either a subscriber, clergyman, missionary, or justice of the peace, or be accompanied by a doctor's card or line of recommendation.

Reviews and Notices of Books.

Cancer of the Stomach: a Clinical Study. By WILLIAM OSLER, M.D., F.R.S., F.R.C.P. Lond., and THOMAS MCCRAE, M.B. Tor., L.R.C.P. Lond., of the Johns Hopkins Hospital, Baltimore. London: H. K. Lewis. Royal 8vo. 1900. Pp. 157. Price 6*s*.

THE presence of the name of Professor Osler on the title-page of any book is in itself sufficient to command attention for the work and a close examination of the volume before us has fully justified the expectations to which his name gave rise. We have in recent years heard much of the operative treatment of malignant disease of the stomach, and especially in the beginning of 1900 Professor Mayo Robson put before us the very latest views as to the surgery of this affection, but so far as we are aware very little has been lately done to give a general view of the present state of our knowledge as to the symptomatology and diagnosis of this disease. We therefore cordially welcome the appearance of this work, especially as it comes from the pen of so eminent a clinician. The statistics and descriptions in this volume are based chiefly on a series of 150 cases of primary carcinoma of the stomach at the Johns Hopkins Hospital.

In the opening chapter we find a very full discussion of

the important question of the alleged increase of malignant disease, and the authors arrive at the conclusion that the increase is real but that the returns at present available do not justify a positive conclusion that there has been any special increase of cancer of the stomach. The importance of heredity in the etiology of malignant disease is held nowadays in much less estimation than was the case only a few years ago, and it is interesting to note that of the cases on which the descriptions in this volume are based in none of the 23 cases occurring before the age of 40 years was there any family history of cancer. It appears also that the influence of previous disease of the stomach such as chronic dyspepsia and gastritis is not of much moment in the production of malignant disease of that organ.

About 6 per cent. of the authors' cases occurred before 30 years of age, and from all sources six cases have been recorded in patients under 10 years of age, the youngest being only 40 days old at death. In fact, there have been recorded in all 19 cases of cancer of the stomach in patients under 20 years of age. On the whole, in the young the course is more rapid than in the old.

With regard to the symptoms the authors have come to the conclusion that the presence or absence of vomiting is not necessarily connected with the presence or absence of ulceration. And of the cases with vomiting only a little more than 28 per cent. had any hæmatemesis. In 26 of the cases the appetite was normal and in two of the cases the appetite was markedly increased. In 87 cases some of the contents of the stomach were obtained for examination, and of those 80 cases showed a complete absence of hydrochloric acid, but in seven it was present, so that this acid may certainly be present and yet there may be a malignant growth of the stomach. The authors consider that the microscopical examination is of considerable importance not only in the fresh but also in stained specimens.

Perforation occurred in 4 per cent. of the present series, and in half of these a localised abscess developed and in one case a communication formed with the cavity of the duodenum and the colon. Metastatic growths by no means rarely form at the umbilicus and two instances of this occurred in the authors' series. Multiple thrombi have been described in some cases of malignant disease of the stomach, and five were met with in this series, and in one case thrombi were present in 14 different veins. A very excellent chapter is that devoted to the study of the tumour itself, and a tumour could be felt in more than 75 per cent. of the cases. In 12 of the cases an atrophic cancerous stomach was present, and in half of these the signs were sufficiently well marked to enable it to be diagnosed during life. It is decidedly rare to find cancer of the stomach in persons dying by accident, but latent cases do occur, and in this series there were eight such cases in which there were no symptoms of a malignant growth.

The first essential in the treatment of carcinoma of the stomach is early diagnosis, for, as has been pointed out by Czerny and Rindfleisch, the presence of a palpable tumour is in itself a contra-indication to radical operation, and though it is to surgery that we must look for even the possibility of complete removal of the disease, yet the medical treatment is by no means unimportant and is in some cases the only treatment which is available. Great attention should be paid to the diet, and on the whole carbohydrates are not desirable as they ferment so very easily. The value of lavage is insisted on, and the authors say that they have never seen any harm result from its use even though ulceration was present. They recommend that it is best employed at night, especially if the patient has "disturbed nights from pain."

Exploratory incisions are advised, but it is rightly urged that they should not be undertaken merely as a diagnostic measure in the case of a patient who is run down and anæmic. As a general rule, the authors tell us, the patients have stood operative interference worse than their general condition would have led them to anticipate, and after operation the impaired powers of digestion may be enough to turn the scale in the wrong direction.

We had marked many other passages for notice, but what we have said is sufficient to show that the work contains a very valuable account of an important affection, and we think there is not a member of the profession who will not derive both pleasure and profit from a perusal of its pages.

The Thompson-Yates Laboratories Report. Edited by RUBERT BOYCE and C. S. SHERRINGTON. Vol. I., Reprints, 1898–1899. Vol. II., Reprints and Reports, 1898–1899. With Illustrations and Plates. Liverpool: At the University Press. 1900.

MOST excellent work has been accomplished in the Thompson-Yates Laboratories at Liverpool and we welcome the appearance of the first two volumes of reports; subsequent numbers are to be issued half-yearly or oftener if sufficient material is ready for publication. They are intended to promote learning and to record research in the various branches of physiology and pathology and thus to carry out the wishes of the founder of these schools. The volumes are edited by Professor Rubert Boyce and Professor C. S. Sherrington, and under such able leadership we have no doubt but that a large amount of valuable material will be published which would otherwise escape the notice which it deserves. Volume I. contains the account of the opening of the laboratories in October, 1898, by Lord Lister who was accompanied on that occasion by Professor Virchow and a distinguished gathering of scientific and representative men. An address delivered before the medical students of University College by the founder of the laboratories, the Rev. S. A. Thompson-Yates, is also published.

The first volume also contains numerous papers and reports on Neurology, Bacteriology, Hygiene, and Morbid Anatomy, also reports on Physiology and Tropical Medicine. Professor C. S. Sherrington contributes articles under the titles of "On the Spinal Animal," "Synopsis in the Peripheral Distribution of some Spinal Nerves," and "On the Innervation of Antagonistic Muscles (Sixth Note)." The second named is a most valuable paper reprinted from the Philosophical Transactions of the Royal Society of London and contains the results of an immense amount of useful research. Dr. W. B. Warrington is responsible for several papers on matters connected with Neurology either alone or in conjunction with Professor Boyce or Dr. E. E. Laslett. Dr. C. Balfour Stewart contributes three Papers on "Haffkine's Plague Prophylactic." Amongst the other contributors are Dr. J. H. Abram and Dr. E. P. Manby.

The second volume contains papers and reports on the same subjects and the reports of the Malarial Expedition to West Africa. One of the most interesting papers is that on "Oysters and Disease," by Dr. W. A. Herdman and Professor Rubert Boyce. It is evident from the result of their experiments and a consideration of all the facts brought to light in recent years in regard to the bacteriology of shellfish and its influence on public health that we must regard oysters, mussels, cockles, and the like, as nutritious food matters, which, from their nature and the circumstances of their cultivation and sale, are liable to become contaminated with organisms—pathogenic or otherwise—and their deleterious products. As the authors point out, when this is once recognised the practical applications are largely a matter of common-sense. Shell-fish must not be taken as food from grounds where there is any possibility of sewage contamination. The fresher they are from the sea the more healthy they are likely to be, and they sh uld

be continually protected after gathering from any possibility of insanitary environment. Only absolutely fresh shell-fish should be eaten uncooked, and those that are cooked must be sufficiently so, being raised to boiling-point and kept there for at least ten minutes.

The publication of these volumes is a decided gain to medical literature and the editors may be congratulated on the success of their efforts.

A Text-book of Pathology in Relation to Mental Diseases. By W. FORD ROBERTSON, M.D. Edin., Pathologist to the Scottish Asylums. Illustrated with 16 lithographic plates and 13 engravings. Edinburgh: William F. Clay. 1900. Royal 8vo. Pp. 380. Price 21*s.* net.

THE need of a systematic work dealing with the pathological changes in the nervous system associated with mental diseases has been long felt. Too long had this department of medicine remained obscure and ill-explored until the foundations laid by the discoveries of Hitzig and Ferrier, Golgi and Ramon y Cajal, Meynert and Flechsig rendered the erection of a stable superstructure possible. In the long series of works which must precede the erection of a rational pathology of mental diseases the present work takes its place as a valuable collection of descriptive studies in pathological anatomy. It is perhaps unfortunate that the author was unavoidably prevented from including in the volume an account of "morbid changes affecting special parts of the nervous system," but this is explained in the preface as due to want of time. The various chapters deal with such matters as methods of post-mortem examination, including histology, morbid conditions of the scalp and ears, abnormalities of the skull, and the morbid conditions of the cerebral meninges, cortex, and blood-vessels. The histological methods given are concise and practical. An interesting description is given of the changes in the ear cartilages in hæmatoma auris. After a brief account of the methods of cranial measurement the morbid conditions of the cranial meninges are dealt with. The term "pia-arachnoid" is employed and a very clear account is given of the relations of this structure to the dura mater and to the cerebral convolutions. The formation of sub-dural false membranes and of pia-arachnoid opacities is clearly described. Dr. Robertson holds that the view of Mickle and Bevan Lewis, one generally accepted—that morbid adhesions of the membranes to the convolutions occur in general paralysis—is erroneous. After a description of the blood-vessels the neuroglia is studied with some minuteness. The account here tends to be diffuse and prolix, physiological and anatomical facts and theories being confusedly mingled, with the result that there is a want of lucidity. The morbid conditions of the nerve-cell are discussed under the headings of terminology, achromatic and chromatic substance, pigment, nucleus, pericellular, and endocellular reticula, classification and mode of connexion of nerve-cells, and this is followed by a brief discussion of the "neuron theory." In his anxiety to give the very latest views on this topic scant justice has been done to the classical researches of Nansen, His, and Forel who have done the most valuable and permanent work in this department. The morbid changes in nerve-cells consequent upon nerve-section, hyperthermia, and experimental anæmia are briefly touched upon, and short paragraphs are devoted to chromatolysis, intracellular degenerations, and myelinic changes in nerve-fibres. Many of the illustrations are taken from the standard works, such as those of Golgi, Lugaro, and others. The work concludes with chapters on brain-weights and the cranial circulation, a brief mention of congenital abnormalities and focal lesions of the brain, general paralysis, syphilitic insanity, alcoholic and epileptic insanity, and idiocy. The work is well printed, being very free from typographical errors, and is a valuable appendix to the library of asylum medical officers and pathologists.

A Cyclopedia of Practical Medicine and Surgery: A Concise Reference Book, Alphabetically Arranged. Compiled under the editorial supervision of GEORGE M. GOULD, M.D., and WALTER L. PYLE, M.D. London: Rebman, Limited. 1900. Large square 8vo. Pp. 1008. Price 42*s.*

THE wide range of medical science and the extraordinary copiousness of medical literature have long ago made epitomes of some kind an absolute necessity for those who desire to take a general view of the subject and to keep pace with modern progress. Many able writers have from time to time done good service in this direction, and of the "Cyclopedia" by Dr. Gould and Dr. Pyle it may be safely said that no treatise which has yet appeared excels theirs as an example of the happy medium between the brevity of a lexicon and the diffuseness which under some editors has made each article an exhaustive monograph and expanded the whole work into several volumes. The authors say in their preface that it has been their object to present in one handy volume, concisely and authoritatively, the more important facts in all branches of medicine and surgery that are of working value to the active practitioner. The task is one for which they were well qualified and for the carrying-out of which valuable experience must have been accumulated by Dr. Gould during the compilation of his monumental "Illustrated Dictionary of Medicine, Biology, and Allied Sciences" (now in its fifth edition). The attainments and professional position of the 74 contributors are a sufficient guarantee that the various subjects have been ably treated, an agreeable aspect of unity pervades the whole work, and it is unquestionable that the object described in the preface has been amply realised. In dealing with a large book of this kind, containing many hundreds of articles alphabetically arranged, it would be impossible on the present occasion to give anything like a general idea of the vast variety of information to be found within its pages, but a brief reference may be made to some of the more important paragraphs. Under letter A, for instance, the account of Abdominal Section covers five pages and gives a satisfactory description of the essentials of the antiseptic methods employed in general surgery, including the sterilisation of instruments and the preparation of the operator and his assistants. Under Alcoholism there are many useful suggestions for the treatment of this condition and delirium tremens. The articles on Amputation, Anæsthetics, and Aneurysm supply in each case a well-arranged and tolerably full *résumé* of the various subjects The more important of the other articles under letter A are Appendicitis, Arteries, and Auto-infection. Under letter C a few of the most interesting paragraphs are those on the preparation and preservation of the Cadaver, the selection and hygiene of Camps (five pages), Cataract, Catheter, Chancroid, Chest (six pages), Cholera, Chorea, Climatology (four pages), Coma (five pages), and Constipation (four pages). Articles longer than any of the foregoing will be found under the headings Brain, Poisoning, Spine, Tuberculosis, Tumours, Urethra, and Urine. We have noticed only one inaccuracy—namely, under the word Water, where balneum maris is explained to be a warm-water bath. Departures from the ordinary English orthography, such as might be expected in a book of American origin, are not numerous and consist for the most part in the substitution of "e" for "æ," and the suppression of the final "e" in "oxide," &c., together with the use of the words "chemic," "pathologic," and the divided "can not." We have not found any important omissions except that there does not appear to be any reference to

diseases of the teeth or dental operations. Perhaps these subjects have been intentionally left out, for the headings Dentition, Teeth in Diagnosis, and Toothache are in their proper places and in each case the description of the respective conditions is adequate. A column is devoted to "Carbon Dioxid," but "carbonic oxid," which is now a frequent ingredient of illuminating gas and seems to have been the cause of not a few fatal accidents, is only catalogued in the list of poisons. Under Malaria and Hemoglobinuria we might have expected to find the familiar phrase "black-water fever," and there is apparently no mention of psilosis, sprue, or Guinea-worm, but these are minor matters and the line must be drawn somewhere, for no single volume of a size convenient for use could possibly be made to contain everything. In fact, it seems almost ungracious to call attention to these points in connexion with a book which we have looked through with so much satisfaction, and it only remains for us to express the conviction that the "Cyclopedia" will prove itself useful for reference and a valuable addition to the practitioner's library. Many of the articles are profusely illustrated and the typography is excellent.

The Morals of Suicide. By the Rev. J. GURNHILL, B.A. London: Longmans, Green, and Co. 1900. Pp. 227. Price 6*s*.

A THOUGHT which forces itself upon the attention of a reader of Mr. Gurnhill's book is "Who will be influenced by it?" The author is alarmed at the proportional increase of suicide in recent years and has in this book addressed himself to combat the tendency, no doubt with the most serious purpose. But why should suicides be amenable to his arguments? Especially does this consideration weigh when it is found that he excuses himself from dealing with the arguments of Pliny, Seneca, and others who have expressed approval of suicide under certain conditions on the ground that "we can scarcely be expected to form our conclusions from ancient classics or take as models for imitation the practices applauded in pagan religions. We have, or at least we believe we have, clearer and truer light to guide us" (p. 19). The position is a difficult one for a writer who wishes to persuade his readers of the error of their ways. And in truth Mr. Gurnhill is himself not quite unconscious of the difficulty. "Full well I know," says he, "that in many cases of suicide—perhaps the majority—neither the dictates of reason nor the precepts of philosophy or religion come into operation." But he thinks that "it is none the less true that the more a man is imbued with sound views as to the moral aspect of suicide the less likely is he in time of trial, temptation, and distress to have recourse to that deadly crime" (p. 71). This, then, is the view with which this book is written. It is a contribution to the task of forming a sound public opinion on a matter which, beyond all question, is a matter of great public concern.

We are not at all disposed to cavil with Mr. Gurnhill concerning the limitations which he chooses to impose upon himself in connexion with his task. If he thinks that he can better reach the section of society to which he addresses himself by refusing to discuss his position with those who do not accept the Athanasian creed we are quite prepared to take him at his own valuation and, so far as in us lies, to recognise a serious effort to spread sound views of morals whether the area of operations be extended or circumscribed; and we perceive that Mr. Gurnhill has some notable qualifications for the task which he has undertaken. He is a scholar and is well read in the subject of which he treats. His scholarship, moreover, is of that literary order—much undervalued at the present day—which enables him to write with perspicuity and force, so that what he says is said pleasantly and to good purpose. But with all these qualifications for his task he has one capital defect. He deals with his subject in that meditative, uncritical—we had almost said absent-minded—style which is the besetting sin of clergymen and the vice of homiletic writing. In fact we have seldom seen so striking an example of want of thoroughness as is furnished by this book. Here is a volume of over 200 pages, devoted to the morals of suicide, written from the standpoint of a Christian clergyman who insists much, and naturally so, upon the example left by the Author of the Christian religion, and yet from cover to cover there is not a word about that awful problem—the duty that sometimes corners the true Christian and good citizen—of laying down his life. Suicide in this book means nothing but the petulant act of the disappointed man who rushes on his fate. The tragedy, the problem, the unselfish dread of becoming burdensome or of cankering a young life with the infirmity of an old one—these things do not exist for the author, who can speak of suicide only with horror as "this deadly sin" and is sanguine that it will become less rampant if the Christian churches can agree about the three creeds (p. 197). It is a disappointing book.

JOURNALS AND MAGAZINES.

The *Monthly Review* for January, 1901, is an excellent number, sustaining the reputation which Mr. Murray's sumptuous magazine has already won for itself. The two editorial contributions, "Unity and Uniformity" and "The Little Englander," will especially commend themselves to medical readers by their sanity and good temper. Our profession have much experience of the really ill-effect that the acerbity of politics has had upon the public health, and as an antidote we are able confidently to recommend the articles to which we refer. By reading them the party politician will learn to his surprise that "Imperial" does not mean everything that is hall-marked by the Carlton Club; that many of the proudest names in our history have regarded the perfecting of England as an admirable method of increasing the value of our rule and maintaining the respect of greater Britain as well as of foreign nations; and that no section or school of political thought has the monopoly of honesty, good intention, and patriotism.

The *Cornhill Magazine* for January, 1901, has an article from Dr. Conan Doyle's pen which shows the medical novelist in a very favourable light as a controversialist. The author of "The Great Boer War" in his valuable book criticised our military administration, as it came under his own eyes when serving with the South African Field Force, his criticism taking the shape of a short but thoughtful sketch of a method by which, it seemed to him, the military force of this country might be made more formidable without an increase of expense. His remarks entailed upon him some rather severe reflections from certain military experts, two of whom took up the position that military affairs should be left to military men—that, in fact, as Dr. Conan Doyle says, "civilian comments are of the nature of impertinence." With this contention, which is tantamount to a claim for the art of war that it is in every branch and twig an exact science, Dr. Conan Doyle makes short work. His rejoinder is studiously fair and polite, but he maintains his original position and in our non-military opinion, which may or may not be impertinent, there is so much to be said for Dr. Conan Doyle's scheme that we trust soon to hear of its endorsement, in part at any rate, by responsible persons.

The *Pall Mall Magazine* for January, 1901, starts under new editorship, but shows no falling away from the excellent position which it has won for itself. It is full of good things and capitally illustrated. The reproductions of the works of Rodin, the impressionist French sculptor, will

be of interest to anatomists. Mr. Winston Churchill's essay on the British officer is readable and reasonable. An article upon Flanders lace makes us regret the days when throughout the length and breadth of a large tract of England some of the finest lace in the world was made by the villagers. To the medical officer of health and the practical sanitarian, struggling with the evils of urban over-population, it must seem an extraordinary thing that such an industry, so pleasant, so well-paid, and not requiring of its operatives more than the most distant connexion with a market, should have been allowed to die out. Political economists can doubtless give a reason for this. We cannot; we can only regret the fact.

Analytical Records
FROM
THE LANCET LABORATORY.

(1) TABLOIDS, (a) BENZONAPHTHOL, (b) THREE SYRUPS AND (c) CALOMEL; (2) HYPODERMIC TABLOIDS; (3) OPHTHALMIC TABLOIDS; AND (4) SOLOIDS OF POTASSIUM PERMANGANATE.

(BURROUGHS, WELLCOME, AND CO., SNOW-HILL-BUILDINGS, E.C.)

BENZONAPHTHOL has recently been tried with some success as an intestinal antiseptic in fermentative dyspepsia, in typhoid fever, and dysentery. It is a true molecular compound of benzoic acid with beta-naphthol. It is insoluble in water and in acids but soluble in alkalies. It thus escapes decomposition in the stomach, but is resolved in the intestinal tract into benzoic acid and naphthol. The tabloid contains five grains of the derivative, which in this form is very convenient for administration. A combination of the well-known syrups—namely, Easton syrup, the compound syrup of hypophosphites, and the compound syrup of phosphate of iron—is represented in the tabloid called "Three Syrups." The equivalents of these are 15 minims of each of the first two syrups and 30 minims of the compound syrup of phosphate of iron. We have carefully examined chemically the constituents of this interesting combination and the presence of each and all was confirmed; the constituents were found preserved in the fresh state. This speaks well for the composition and probable efficiency of the tabloid, while it is needless to point out the advantage of this combination in the form of tabloid as compared with syrups. A useful tabloid also is that containing three grains of specially purified calomel. Euphthalmine has recently been introduced in ophthalmology as a favourable substitute for atropine. In the form of hydrochloride, present in the ophthalmic tabloid to the extent of one-fortieth of a grain, euphthalmine is said to produce when applied to the conjunctiva full dilatation of the pupil with but moderate disturbance of accommodation and no change in intra-ocular pressure. Its advantages are such that it appears to be especially suitable for ophthalmoscopic examinations. The tabloid dissolves immediately it is placed upon the conjunctiva. Amongst new additions to hypodermic tabloid products are morphine sulphate a quarter of a grain, and strychnine sulphate $\frac{1}{60}$th of a grain, a combination which has been used in phthisis with cough and cardiac weakness. These drugs have also been employed previously to administering an anæsthetic and are even stated to render less chloroform necessary, whilst the presence under these circumstances of the cardiac stimulant strychnine is considered an advantage. For hypodermic use also morphine sulphate has been combined with ergotinine citrate in the hypodermic tabloid in order to favourably modify the action of the hæmostatic. Lastly, a new soloid of potassium permanganate has been prepared containing one grain of the salt. It is useful for the preparation of a harmless antiseptic and disinfectant solution or for the ready preparation of an injection, lotion, or gargle.

(1) PEROXINE; (2) PEROXINE LOTION; AND (3) PEROXINE OINTMENT.

(THE NEW INDUSTRIAL REFINING CO., LIMITED, 8, PRINCES-STREET, E.C.)

These are all very interesting products, the active constituent of which is peroxide of hydrogen. Peroxine itself is a colourless liquid with an agreeable smell and is capable of yielding nearly twice its volume of oxygen. According to further analysis it contains nearly 1 per cent. of an essential oil which has become oxygenated during the course of manufacture. It is owing probably to the presence of this essential oil that the liquid is practically permanent in oxidising power and properties. Peroxine is intended for internal application. Apart from its marked antiseptic properties it is a real deodorant and cleansing agent. These properties render it useful in certain gastric and intestinal disorders, while it is said to have some oxygenating effect on the blood and thus to be beneficial in anæmia. Peroxine lotion is a stronger preparation, containing, according to our analysis, 5 per cent. of oxygenated essential oil and yielding nearly 10 times its volume of oxygen. It is curious to note the effect of oxygenating an oil, which makes it miscible with water. Thus peroxine lotion is a perfectly clear homogeneous fluid and yet contains 5 per cent. of an essential oil. On evaporating the lotion the oil commences to separate. Ether extracts the oil from the lotion and the oil may be recovered by allowing the ether to evaporate. It still possesses strong oxygenating powers, as is shown by its effect upon chromic acid, permanganate of potassium, &c., in the presence of water. The oil under these circumstances may possibly generate ozone. The lotion is permanent as regards its oxidising strength, owing, doubtless, to the preserving effect of the oil. It is suggested for external use for wounds, skin eruptions, &c., and as a healing application generally. It is a powerful deodorant and antiseptic and effective in cleaning or deodorising foul discharges. Peroxine ointment is a white unguent containing an oxygenated essential oil. The ointment basis is white vaseline. It is a very agreeable ointment to use, soothing and healing on account of its antiseptic and oxygenated properties. It is worth while pointing out that not the least important advantage of these preparations is that while they are powerfully antiseptic and deodorising they are non-posionous.

VAN YSENDYK'S ROYAL NETHERLANDS COFFEE.

(ROTTERDAM. LONDON AGENCY: H. A. KRAMERS AND CO., 23, ROOD LANE, E.C.)

Undoubtedly the frequency with which coffee has been adulterated in the past is a factor which has rendered it less popular as a wholesome and agreeable stimulating beverage than it deserves to be. Even when the coffee is genuine its good qualities depend largely upon its method of manufacture and chiefly in regard to the way it is roasted. Finally, the preparation of coffee in England is not understood. The specimen before us is described as a new coffee. Whatever that may mean it is certainly good coffee and nothing but coffee. It possesses to a degree that peculiar fragrance which makes coffee attractive. It yields a very agreeable infusion, rich in the aromatic products obtained on roasting the berry, containing also a notable proportion of oils of coffee.

LERINA LIQUEUR.

(COVERDALE, POHLMANN, AND CO., 5, MARK-LANE, E.C.)

This is a liqueur said to be made by the monks of the Abbey of Our Lady of Lérins, Cannes, and is well known in the Riviera. The abbey, it is stated, dates from the fourth

century and "was a nursery of learned men, orators, and saints." Like other monastic liqueurs Lerina is a secret preparation, but we have found no constituent in it to which objection could be taken. It is a pale olive-green, syrupy liquid with peculiar delicate flavour. On analysis the liqueur gave the following results: alcohol—by weight 32·87 per cent., by volume 39·47 per cent., equal to proof spirit 69·16 per cent.; extractives and sugar, 33·45 per cent.; and mineral matter, 0·06 per cent. The liqueur has certainly an interesting and ancient history, and doubtless great care is directed towards its preparation and to the choice of its ingredients. Like most liqueurs containing the essential oils of plants or flowers it is an agreeable "digestive," acting as a carminative and producing a sense of comfort in the gastric centre after a meal.

IMPREGNATED WAX VESTAS.

(LONDON WAX VESTA CO., THE POINT, WANDSWORTH, S.W.)

We called attention in THE LANCET of Nov. 24th, 1900, to the danger arising from the ignited heads of wax vestas flying off on striking. Of course, a good deal depends upon the kind of rubber upon which the match is struck, but undoubtedly the tip is often at fault. It seems to us that it would be useless to offer a remedy in the shape of a rubber admirably adapted for the purpose because the public demand a match which will strike anywhere or on any surface without regard to its suitability for the purpose. Our remarks have been endorsed by the above company who have turned their attention to the preparation of matches which shall not lose their heads when struck. The resulting match is known as the impregnated wax vesta. We have tested a number of these matches by striking them on all sorts of surfaces and sometimes on fairly sharp points, or series of points, which, of course, is a severe ordeal. The impregnated vestas satisfied these tests and therefore their adoption, could it be universal, would largely, if not entirely, remove the objectionable and dangerous tendency of the red-hot heads to fly off in all directions on striking.

(1) "KUMOFF" AND (2) "NETTWAR."

(THE WALL-PAPER CLEANING SYNDICATE, LIMITED, 22, GLASSHOUSE-STREET, PICCADILLY-CIRCUS, W.)

The above are the names respectively of a wall-paper cleaner and a paint and varnish cleaner. "Kumoff" is a plastic substance resembling putty but reddish in colour and smelling distinctly of oil of cloves. Apparently it is a proteid substance akin to the gluten of wheat flour. It acts mechanically and after the manner of a piece of soft bread or dough in removing patches of grime from wall-paper or ceilings. "Kumoff," however, is far more effectual than bread or dough. It rapidly removes dirt and when carefully used transforms a blackened ceiling or paper to its original clean condition. "Kumoff" distinctly belongs to sanitary preparations: it works well and is cleanly. The bacteriology of "Kumoff" after it has been used would be interesting; it would, of course, teem with microbes, millions of which must have their habitat on walls and ceilings. "Nettwar" is a pink, soapy fluid containing some carbolic acid. It is a cleansing application for painted and varnished surfaces. Both preparations are essential to a sanitary equipment.

LIME JUICE WHISKY LIQUEUR.

(L. ROSE AND CO., LIMITED, 41, MITCHELL-STREET, LEITH.)

The analysis of this somewhat novel liqueur was as follows: absolute alcohol—by weight 29·87 per cent., by volume 36·04 per cent., equal to proof spirit 63·17 per cent.; sugar and extractives, 33·03 per cent.; mineral matter, 0·03 per cent.; and acidity reckoned as citric acid, 0·75 per cent. The whisky employed is stated to be malt spirit 10 years old. Judging from the smooth flavour of the liqueur and the spirit obtained from it on distillation this is probably a fair description. We could trace no objectionable preservatives; and, in fact, the alcoholic strength would render the addition of a chemical preservative quite unnecessary. The liqueur is somewhat syrupy and sweet to the taste, but in it is preserved the pleasing aroma of lime fruit. It is an agreeable and wholesome liqueur, having in particular to recommend it that its composition is declared. Lime juice and whisky are, by the way, not quite an unheard-of association.

INVALID SPECIALITIES, BEEF-TEA, JELLIES, ETC.

(POULTON AND NOEL, BELGRAVIAN WORKS, BREWERY-ROAD, N.)

We are glad to notice that the practice is increasing of inclosing invalid specialities in glass vessels and not in tins. Except the home-made beef-tea, which was submitted to us amongst other things for examination by the above firm, the jellies and the essence of beef were contained in air-tight glass jars. The beef-tea gave the following approximate analysis: water, 92·74 per cent.; total solids, 7·26 per cent.; mineral matter, 0·66 per cent.; and nitrogen, 1·13 per cent. The tea was opalescent but did not contain muscular tissue. Considering the proportion of water its real nutritive power is decidedly low. It possesses, however, a pleasant beefy flavour and is agreeably stimulating, serving to rouse also the appetite for more solid nutriment. The beef essence gave on analysis the following results: water, 86·30 per cent.; total solid matter, 13·70 per cent.; mineral matter, 3·76 per cent.; and nitrogen, 2·04 per cent. This is a well-prepared essence of agreeable flavour and helpful to invalids or those with enfeebled digestive function. It is perfectly clear and free from the smell and flavour of a preparation concentrated by heat. It contains, excluding gelatin, a comparatively small proportion of proteids. The calves' feet jelly was excellent in all respects, possessing a delicate flavour and consistence calculated to appeal to the fastidious palate.

FRANZISKANER LAGER BEER.

(J. SEDLMAYR, MUNICH, AND ANDRÉ STAHL AND CO., 47, MORTIMER-STREET, W.)

It is well known that some very definite control is exercised over the production of beer in Bavaria. It must be made from malt and hops only. The specimen before us is produced at the celebrated Leistbrau in Munich, and according to our analysis exhibits the usual excellent composition of Munich beer. Our analysis was as follows: extractives, 6·02 per cent.; mineral matter, 0·20 per cent.; alcohol—by weight 4·62 per cent., by volume 5·78 per cent., equal to proof spirit 10·13 per cent. The beer was evidently Pasteurised and we could find no chemical preservatives or, as we suppose we ought to add now, any trace whatever of arsenic. It is noteworthy that Munich beer, though less alcoholic than English beer, contains a much larger proportion of the nutritive extractives of malt. The specimen examined was excellent and in sound condition, possessing those characteristics of flavour and palatability for which Munich beer is esteemed.

NEW HOSPITAL FOR MONMOUTH.—At the annual meeting of the subscribers of the Monmouth Hospital, held on Dec. 22nd under the presidency of Lord Llangattock, it was stated that £4000 would be required for the erection of the new hospital and that £2356 had been already subscribed.

ROYAL MINERAL WATER HOSPITAL, BATH.—The committee of this hospital are making an earnest appeal for £6000 towards carrying out some extensive alterations and improvements in the institution. The hospital was opened for the reception of patients in 1742, since which time 76,000 poor persons have been admitted, of whom about 65,000 have been relieved. Patients are admitted without any subscribers' recommendations.

THE LANCET.

LONDON: SATURDAY, JANUARY 5, 1901.

1901.

WE do not propose here to make an attempt to summarise the scientific progress of the past century within the limits of a leading article. Our contemporary, the *British Medical Journal*, in an excellent special number published at the end of 1900, gave an account of the march of medicine during the past 100 years, and able and inclusive as the story there told is, we are certain that its authors would be the first to say that their difficulty was not what to say but what to omit. Yet with the dawn of a new century it is fitting that we should glance back over the old one, to see in what ways we have the right to call ourselves better than our fathers. Obvious progress, of course, there has been in most of the departments of human intellect, and this is especially true of that department of the intellectual process known as science. In art we may say without contradiction that we have not progressed. Compare any modern building with Durham Cathedral in ecclesiastical architecture, with Magdalen College, Oxford, in collegiate architecture, with Hatfield or Haddon in domestic architecture; put an ivory or a wooden carving of the middle ages beside a modern one, compare the textile fabrics of Venice in her glory with those produced nowadays (other than those that are openly imitations), and it will be seen that here we have made no progress. But in science the case is very different. Here we have learned from the efforts and mistakes of those who have gone before us, and in every instance and in every department of science we at the beginning of the twentieth century are far more advanced than was the race at the beginning of the nineteenth. The steam-engine remained for centuries a mere toy: from the time of HERO, B.C. 120, to the time of the Marquis of WORCESTER no use was made of the expansive powers of the vapour of water, and from 1663 until the era of WATT and STEPHENSON but little progress was made. But within the last 100 years we have slowly moved onwards from the "Rocket" of STEPHENSON and the little "Comet" of BELL to the mighty locomotives of our railway companies, and to H.M.S. *Viper* with a speed of 35 knots per hour. And yet the principle by which the latter is driven is the steam turbine first described by HERO over 2000 years ago, a fact which shows that what each generation deems to be perfection is only an example of transition.

In those departments of science with which we are nearly concerned—namely, medicine and surgery in their widest applications—we are more obviously in a state of transition than we are in any fields of exact knowledge. Surgery has advanced to a greater degree than medicine, but this is mainly because surgery, as its name states, is to some extent a handicraft. The technical methods of our day are far ahead of those of our ancestors. The discovery of anæsthetics and the perfecting of the antiseptic or aseptic system have made feasible operations the very thought of which would have stayed the hands of our ancestors. It is not that modern surgeons are necessarily better anatomists, or better practitioners than their predecessors, but that they have better tools, and a cleaner *milieu* in which to work. These facts account for the death-rate of surgical cases having shrunk in some instances almost to a vanishing-point. But we are not belittling the surgery of to-day. As a handicraft it has progressed notably. But surgery is not only a handicraft—it is also a science, and modern surgeons have progressed on truly scientific lines, for they have used the accumulated experiences of past leaders while benefiting by recent discoveries. With regard to medicine the progress has not been so obvious during the century. The identification of certain specific germs and the recognition of the evil powers of certain parasites, like the differentiation of typhoid fever from typhus fever, by leading to treatment based upon pathology have saved thousands of lives, and bid fair to save a yet larger number in the future. And small-pox has been robbed of its terrors by vaccination, but vaccination is prevention and not treatment, and it is in prevention that the modern progress of medicine has been made. And everything goes to show that it is in this direction that the main advances will be made during the twentieth century. Not that medical treatment is to be despised, for if the *materies morbi* gains access to the body it can be removed only in one of two ways—either by the knife or its equivalent, or by the natural defences of the organism aided by rest, careful dieting, and in some cases drugs, including such medicaments as the antitoxins. No one of us can cure a fever by medicines, but we can and do put the sufferer into such a position that his bodily powers are placed in the best possible state for coping with disease.

In olden times the medical man was looked upon as a wizard. When summoned to the bedside of a patient he dressed himself in a fantastic dress, rattled strings of bones, beat a drum, and howled invocations to the devils which were supposed to be causing the disease. Similar things were done in communities that esteemed themselves civilised and since the mediæval birth of learning; but such a bedside manner was quite in accordance with what was expected of the medical man; and sometimes the patient recovered. As time went on most of the fantastic accessories disappeared, but a hundred years ago there were still considered by the majority of observers to be special remedies for all special diseases. This last belief is by no means extinct at the present day among a large section of the public, where the "doctor" is someone who gives a "bottle" selected according to the particular illness on hand. The best "doctor" is here considered to be he who can most quickly give a name to the disease, for if he can do that at once he need have no hesitation about which "bottle" to administer; it follows, therefore, that the quack has an enormous advantage over the medical man, as the quack, unhampered by knowledge, is always ready with diagnosis and specific. The practice of medicine by taking prevention as its chief aim has effectually disassociated itself from all quackery, and the medical practitioner of to-day has earned the

right to be looked upon as one having a duty to perform to the State. Consider what the plague of London in 1665 meant. Nothing but the efforts of medical men prevented the plague of Glasgow in 1900 meaning the same thing. We give an instance of signal success, but how much remains to be done. Enteric fever and plague still ravage India, diphtheria and scarlet fever still cause many deaths in our great towns, and tuberculosis still cuts short many a life. With the last-named disease we seem to be about to be able to cope successfully; at any rate the new century will see an organised attempt in these islands to deal with the national infliction, while there are grounds for hoping that the prevention of malaria in some forms is within sight. The mention of this last disease reminds us that stress must not be laid upon the value of prevention to the neglect of remedial measures. Just as quinine is of proven value in malaria, so there are many remedies of tried repute for other pathological conditions and morbid symptoms. While the ideal of medicine is the prevention of disease, the practice of medicine consists in the application of general treatment and special remedies. How much can be done for the sufferer by a medical man having all the modern resources of therapeutics at his command we all know—the public and the medical profession alike. How those resources may be increased by physiology, chemistry, and the comparatively new science of bacteriology in the near future we can only guess.

During two-thirds of the past century THE LANCET has tried to be, and has we hope succeeded in being, a faithful and impartial chronicler of progress in medicine, in surgery, and in hygiene. We have noted mistakes and failures as well as successes, and by both our readers as well as ourselves have profited. Our egoism will, we hope, be pardoned if we point out that to THE LANCET and its Founder are due such reforms in the profession of medicine as the Medical Act, the Anatomy Act, the provision for a medical education of the best kind, and the banishment of nepotism and favouritism from the great hospitals. All these reforms took place during the century that has gone, and to them is due the enormous change that has taken place in the position occupied in the public eye by the medical practitioner. It only remains for us to say, on the threshold of the new century, that we are honestly proud of the long and steady support which THE LANCET has received since its commencement from the medical world, and that we shall strive during 1901 to work as we have worked through the past 77 years for the welfare and advancement of the profession that we love.

The Sanitary Administration of the County of London.

IT is satisfactory to gather from the annual report of Mr. SHIRLEY MURPHY, the medical officer of health of the County of London, which was published last week, that the county maintains its sanitary condition. This state of affairs may be regarded as dependent in no small degree upon the ability and zeal with which Mr. SHIRLEY MURPHY and his officers are known to approach the many difficult problems that are necessarily involved in the efficient sanitary administration of a crowded area like London and its environs. Supplementary reports are contributed by Dr. W. H. HAMER on the sanitary administration of Kensington, and by Dr. C. W. F. YOUNG on the sanitary condition of cemeteries and burial-grounds. Dr. HAMER considers that the staff of sanitary inspectors in Kensington should be increased, and Mr. SHIRLEY MURPHY endorses this view. Dr. YOUNG found it not possible to estimate accurately the length of time for which the existing provision of burial-grounds would suffice, but he shows that there would be advantage in steps being taken to encourage methods of interment, advocated by Sir F. SEYMOUR HADEN and Dr. G. V. POORE amongst others, which aim at the speedy dissolution of the body. For the present we have not space for dealing with the interesting statistical returns contained in Part I. of the report, which deal mainly with the question of population, with the figures of the births, marriages, and deaths in London, and with the prevalence of disease in the county. These statistics represent an enormous amount of careful, we might almost say loving, work, and are entitled to separate treatment on another occasion; for the present we must be content with referring to the various matters of administration which are dealt with in Part II.

Interesting and terrible disclosures have been made during the year in connexion with the trafficking of those deliberate fiends who attempt to sell, and too often succeed in selling, animal food absolutely unfitted for human consumption. We take, for example, the following cases. Mr. SHIRLEY MURPHY had occasion to inquire into the business of a knacker who was sending animal flesh to certain premises in the east of London. The occupier of these premises was presumably a dealer in cat's meat, but suspicion was aroused that this particular consignment of flesh was intended for human consumption, since it was dressed in a manner which was consistent with this view. It transpired that among the customers of the occupier of these premises was a "manufacturer of high-class meat pies." It is not surprising, therefore, that Mr. SHIRLEY MURPHY is once again led to emphasise, as he did in his last report, the need for adoption in London of a system of meat inspection similar to that of many large foreign towns. There is no systematic inspection of meat in London, and until an efficient system is adopted there is not the least doubt that unsound meat will be freely introduced from all parts into London, to the prejudice of the poor who at present receive no assistance from the authorities. The sale of tinned foods to the public in a state of decomposition forms another and similar instance of outrage of the commonest instincts of humanity. Tins of milk, salmon, sardines, soups, rabbits, compressed beef, and vegetables, bearing every evidence of the rottenness of their contents, are, it will be seen from this report, bought in large quantities from importers who have rejected them for their own purposes. This garbage eventually finds a sale amongst the poorer classes. The tins are pricked to let out the putrid gas, are resoldered, have fresh labels pasted upon them, and the appearance of a wholesome article is thus given to them before they are retailed to the defenceless poor. The iniquity of one transaction detailed in the report was emphasised from the fact that the invoices produced

were marked "pigs' food," but the infamous dealer failed to show that he had ever sold a tin in his life for pigs' food. By recounting in detail one such story Mr. SHIRLEY MURPHY proves among other things the desirability of the London County Council organising larger powers of control over the sanitary condition of premises on which food is prepared for sale. There can be little doubt that food has often proved poisonous on account of having been exposed to a filthy environment during preparation, as, for instance, exposure to the gases or effluvia from sewers and drains. We might mention that such powers are urgently needed in the case of premises where ice-cream is manufactured. "Deaths from ice-cream" is a familiar heading in the summer newspapers, and so long as the filthy conditions of the Italian quarter in Hatton-garden, described by our Sanitary Commissioner some years ago, are maintained, there can be no wonder that fresh victims are added to the list. We have suggested the plan of registering persons engaged in the preparation of all food-stuffs, and some such means of reform will have to be undertaken.

Sanitary authorities in the County of London appear to be moving tardily in the matter of providing public means of disinfection of infected articles. It is to be hoped that the constitution of the new metropolitan boroughs will bring to an end the delays which have been primarily responsible for the unsatisfactory arrangements which have hitherto existed in many parts of London. A further important point in this matter is mentioned by Mr. SHIRLEY MURPHY—that is, the need for provision of laundry accommodation in connexion with the apparatus for disinfection, so as to obviate the necessity of householders sending to public laundries articles which are infectious. The satisfactory removal of house refuse, though formerly a bugbear of all sanitary authorities, is steadily extending. The effect of the introduction into districts of a system of weekly calls at each house for the purpose of removal of refuse, instead of the old method of the dust-cart perambulating the streets and calling only at houses in which the need for collection is manifested by the exhibition of a D-card or on request of the householder, is shown by the reduction in the number of complaints dealt with by the sanitary authorities. In some districts, however, improvement is still widely needed in regard to dust collection. Householders are sometimes negligent in this matter themselves, in which case, of course, they are to be blamed for any insanitary development, the only regrettable thing being that the offenders against decency are not likely to be the only victims of their criminal carelessness.

The flooding from sewers—notably in Kensington, Newington, Battersea, and Plumstead—has led the County Council to adopt certain resolutions in regard to a scheme for providing additional outfall sewers. This would involve for both sides of the Thames an expenditure of nearly £3,000,000 of money. It is to be feared that London sewers are taxed to the very utmost, and, if we mistake not, we have in these occurrences only the beginnings of a future great problem which must be seriously faced. Nuisances arising from sewer ventilation continue to be complained of, but the complaints cease as level ventilators are closed and shafts erected to take their place. The pollution of the river Lea calls for serious attention owing to the unsatisfactory condition of the effluents from the sewage-farm at Walthamstow and the sewage works at Leyton, but apparently no progress has yet been made in the direction of improvement by the responsible parties. The pressure of a central authority is very properly suggested by Mr. SHIRLEY MURPHY and we shall be glad to hear of such pressure in operation.

A supplementary report embodying the results of the examination of cows in London cowsheds, both generally and in regard to tuberculous disease of the udder, is contributed by Mr. P. J. SIMPSON. This gentleman's appointment was recommended by the Public Health Committee so as to give effect to the new Order of the Local Government Board relating to tuberculous disease of the udder of the cow. As a result of inspection Mr. SIMPSON and his two colleagues recommended (*a*) that for the purpose of giving effect in London to the Dairies, Cowsheds, and Milkshops Order of 1899 the cows in London cowsheds should be examined by a veterinary surgeon and two assistants at intervals of three months and suspected cows at more frequent intervals; and (*b*) that 100 samples of milk should be sent for bacteriological examination. These recommendations were ultimately adopted by the Council. Mr. SIMPSON found that out of the 5144 cows that were inspected 4464 were free from disease or abnormalities of the udder.

Continued activity is maintained in regard to checking the smoke nuisance. Proceedings, we are glad to hear, were successful in all but a few cases. The chief officer of the Public Control Department of the London County Council (Mr. ALFRED SPENCER) adds in his supplementary report that "so many improvements have been made in recent years in furnace construction that with proper care in stoking no nuisance need be caused." That describes exactly the attitude we have adopted on this question for several years past.

We have made no attempt to do more than indicate the contents of Mr. SHIRLEY MURPHY'S vast record of work done. A dozen subjects, many of them every whit as important as those we have selected for notice, are not here alluded to, while in numerous places the report calls for exhaustive consideration by the physician and statistician alike. But we have said enough to show that our mighty metropolis at the beginning of the new century is receiving excellent sanitary care. The task before the medical officer of health of the County of London and his assistants is tremendous, but supported as they are by the consciousness of successful labour in the past and of hearty coöperation by the new boroughs in the future, they are sure to give a good account of themselves.

The Employment of Unqualified Dispensers.

THE finding of the General Medical Council in the case of Dr. JOHN M. THOMSON which we reported in THE LANCET of Dec. 8th, 1900, p. 1695, is one of much importance to general practitioners, especially those of Scotland. In fact, in Scotland the matter constitutes a burning question. Meetings of the profession have been called in different places, at each and all of which certain speakers have spoken with much warmth. At one such meeting, that of the

Glasgow Southern Medical Society, where Dr. WILLIAM WATSON presided over a crowded assembly, the *locus standi* of the General Medical Council was questioned. and further meetings, where presumably the same feeling will be manifested, are promised in the near future. Although we deprecate any undue warmth in the discussion of this question we can readily understand that the practitioners of Scotland have felt embarrassed by the decision of the Council. It has come upon them suddenly. Dr. THOMSON himself had only short notice of the complaint made against him. The President of the General Medical Council explained that this apparent hurry was due to the view that it was kinder to Dr. THOMSON to bring the matter to an issue than to leave it in suspense for six months. This is quite intelligible, but nevertheless the question is a new one. There may not be much to say on the side opposite to that taken by the General Medical Council, but the matter will be all the better settled by the avoidance of undue haste in the future stages of the case, and by due consideration of those affected by the decision of the disciplinary body of the profession.

Let us state shortly and clearly the nature of the complaint against Dr. THOMSON as well as the action taken by the General Medical Council. The complaint was that, being a registered medical practitioner, Dr. THOMSON employed as assistants—he had had at least two such—"for the sale of drugs and poisons persons who are not qualified to act as chemists or pharmaceutical assistants, and thereby caused such persons to commit breaches of the Pharmacy Act." The first thing that occurs to anyone in reading such a complaint is that it would come more naturally from the Pharmaceutical Society than from the General Medical Council. Why should the General Medical Council do the work of the Pharmaceutical Society? The question is a natural one. The druggists are constantly invading the domain of the medical man and doing his work—diagnosing and prescribing as if they were educated and entitled to do so. The medical profession is badly treated by many pharmacists qualified under the Pharmacy Acts, and it is natural to ask why the General Medical Council should act, or seem to act, against a registered medical practitioner for an offence under the Pharmacy Acts. But there is an answer to the question. The Pharmaceutical Society had instigated no less than 46 prosecutions of unqualified druggists' assistants and had done so with little effect. The law is that the actual seller of the drug or poison is to be convicted, not his principal. The actual seller is generally poor and the practice of employing an unqualified person is very general in druggists' shops. Accordingly, the fine imposed is very nominal and the custom goes on unchecked. In other words, the Pharmacy Acts in Scotland are largely nullified. Obviously the evil calls for an amendment of the Pharmacy Acts, making the principal—whether chemist or medical man—responsible for the acts of his agent. But here comes in the action of the General Medical Council. Clearly it has no jurisdiction over druggists or the proprietors of druggists' shops. But when a medical man engages an unqualified person to take charge of a dispensary for eight hours out of 10 daily, who sells all sorts of drugs even to children—including half an ounce of laudanum of which no record was kept in a book—it is surely time to ask if the General Medical Council can do nothing to stop a practice so dangerous to the public and so discreditable to the profession. If the law cannot effectually touch the druggists at least the General Medical Council can check such dangerous practices among those who owe it allegiance. The General Medical Council allows the legitimate use of a dispenser to make up the prescriptions of the practitioner who employs him on the supposition of direct personal supervision of the work done and of the responsibility of the principal. But all these conditions fail in Dr. THOMSON'S case. The principal is absent for eight hours out of the working day, and the drugs are supplied irrespectively of medical prescription. And a certain sanction is given to the business by the fact that the proprietor of the shop is a medical man. That the premises are owned by a medical man is taken to mean that he is present and is answerable for all that is done. No medical man can really approve such a system. There is nothing medical or professional about it. It is distinctly contrary to the public interest that a medical man should give his sanction to a system so loose and so likely to lead to the injury of the public. In this particular case the laudanum, to the sale of which allusion has been made, was used suicidally by a woman in the sufferings following upon childbirth. This, of course, was an exceptional tragedy, but it arose out of an habitual state of affairs and is a telling argument against such a state.

The General Medical Council could scarcely be expected to act otherwise than it did when such a system was brought under its notice. It is responsible to the public for the regulation of the professional conduct of registered practitioners by certain great principles, and it must not evade the delivery of judgment in individual cases. Accordingly in this instance it found the complaint against Dr. THOMSON proved. It very properly adjourned the further consideration of the case till May. The Council, through its President, expressed its sense of the gravity of the charge, and gave Dr. THOMSON an opportunity to fully consider his position in the interval. Dr. THOMSON will act wisely by looking at this question from the standpoint of the General Medical Council and of the great majority of the medical profession. He must dismiss from his mind all idea that he has been sacrificed to the little jealousies of druggists, or to over-anxiety on the part of the General Medical Council to do the work of the Pharmaceutical Society. The General Medical Council has to provide that the action of medical men shall be regulated on such principles as will secure the welfare and safety of the public, therefore it was bound to prohibit him from using unqualified men in the manner that he was doing. We have no wish to be hard on Dr. THOMSON. In keeping a shop for the sale of drugs and poisons over the counter, in trade fashion, and without prescribing, he only did what many others of his profession do in his division of the kingdom. The custom is an old one belonging to more primitive days, and even now in lonely parts it may be capable of some justification. But in general, and at this time of day, it is not one consistent with the welfare of the public or the dignity of

the profession, therefore it must be altered. The practitioners of England have had to learn that they cannot use unqualified assistants. The lesson has been a hard one, involving removal of not a few from the Medical Register. The Council has insisted on this reform in England in spite of the obvious hardships inflicted by it upon the whole class of unqualified assistants and upon not a few practitioners. It must not hesitate to require in the same way that medical practitioners in Scotland, or elsewhere, shall not lend their professional name and status to cover a use of unqualified assistants in an open shop. Such a proceeding is quite different from that of dispensing the private prescriptions of a medical man under his immediate supervision in his private dispensary. Medical practitioners are at liberty to adapt themselves and their terms to their environment and to the modest means of those who need medical advice, but they are not at liberty to use their professional status to defeat Acts of Parliament, and to bring enormous risks at the same time within reach of the public whose health is presumed to be their care.

Annotations.

"Ne quid nimis.

THE NEW YEAR HONOURS.

THE new year's list of honours is remarkable in one way—namely, that no peerage has been conferred. Of those who belong to, or are connected with, our own profession we have to note the names of Thomas Barlow, M.D., F.R.C.P. Lond., and William Selby Church, M.D. Oxon., F.R.C.P. Lond., who have both been honoured by a baronetcy being conferred upon them. Dr. Barlow is a physician extraordinary to Her Majesty the Queen and is also physician to the Household. Dr. W. S. Church is President of the Royal College of Physicians of London and his baronetcy may be regarded as much a tribute to his official position as to his recent services on the Hospital Commission. In this connexion it should be noted that in the Order of the Bath Lord Justice Romer has been made Grand Cross. Lord Justice Romer, it will be remembered, was chosen to preside over the commission of inquiry into the management of the hospitals and other medical matters in South Africa. Among the Knight Commanders of the same order is the name of Sir William Turner, M.B. Lond., F.R.C.S. Eng. & Edin., the President of the General Medical Council. In the Order of St. Michael and St. George, Maximilian Frank Simon, M.D. St. Andrews, late principal civil medical officer of the Straits Settlements, has been made a Companion upon his retirement from office. In the Order of the Indian Empire Major John Crimmin, V.C., I.M.S., has been made a Companion. Among those who have received the honour of knighthood is Hugh Adcock, C.M.G., L.R.C.P. Edin., M.R.C.S. Eng., who is physician to H.I.M. the Shah of Persia, while Colonel James Sutherland Wilkins, I.M.S., and Arthur Neve, F.R.C.S., L.R.C.P. Edin., have been decorated with the Kaisar-i-Hind medal for "public service in India." Mr. Neve is a medical man working at Srinagar, Kashmir, under the Church Missionary Society. Lord Justice Romer's name is not the only non-medical name that deserves mention in THE LANCET. Among the new knights are Mr. Edward Henry Busk, Chairman of Convocation in the University of London, and Mr. Alfred Cooper (of Surbiton) whose philanthropy is known to our readers. Mr. William Jameson Soulsby, C.B., the secretary to so many Lord Mayors of London and secretary to the Mansion House Indian Famine Relief Funds in 1877, 1897, and 1900, has been made a Companion of the Order of the Indian Empire. To all these gentlemen we offer our best congratulations upon their well-earned distinctions.

THE LONDON WATER-SUPPLY OF A HUNDRED YEARS AGO.

VERY great changes have taken place in the water-supply of London during the last 100 years. At the commencement of the nineteenth century a large number of the people obtained the whole of their water from wells. Many houses had private wells, but in addition to these there were a great number of public wells in the streets. These were filled with surface water, and their depth below the ground level was not great. At the present time we are not aware of the existence of any private surface wells from which the water is used for drinking, but there are a fair number of deep wells which pass through the London clay into the chalk and from these excellent supplies are still obtained. One public pump still exists in Kensington Gardens, and there is one in Aldgate, but for many years the latter has been supplied with filtered water. At the beginning of the century it was quite a common thing for the inhabitants who lived near a public pump to send there for the supply which they required for drinking and for household purposes. Many of the wells became contaminated and towards the middle of the century the incidence of cholera in the neighbourhood of the pump in Broad-street, Soho, led Dr. Snow to make those careful researches which led to his discovery of the chief method by which cholera was spread in London. The oldest organised system of water-supply which existed in the metropolitan area was probably that of Westminster, for in the year 1800, and, indeed, till the middle of the century, the Abbey precincts obtained their water from Hyde Park. Some parts of Westminster were at that time supplied by the Chelsea Company, whose reservoirs were then situated in Hyde Park and in the Green Park. The site of the former is still plainly to be seen near Park-lane, not very far from the Duke of Westminster's house. It has been converted into a sunk garden. The Green Park reservoir was not far from Piccadilly, nearly opposite Half Moon-street, but the exact site is not at the present time marked by any visible trace. Other parts of Westminster were supplied by the New River Company, and by the York Buildings Company which pumped water directly from the Thames. The works of the latter company were near the Adelphi Buildings, and their tower is a prominent feature in all the contemporary drawings of that part of the north bank of the Thames. The company's customers were chiefly the residents in the Strand and in the adjoining streets. At this time (1800) much building was going on in Marylebone, which was not well supplied by the New River Company, and during the next few years two companies, the West Middlesex and the Grand Junction, were started to supply this important new residential area. Holloway and parts of Tottenham Court-road derived their water from Hampstead. In the City of London the New River Company had no monopoly and the London Bridge Waterworks Company still had a considerable number of customers whom they lost a few years later because they were unable to supply water at a pressure sufficient to reach the upper storeys of the houses, a condition which had become necessary in consequence of the exigencies of more modern sanitation. The East end of London in the year 1800 was supplied by waterworks situated at Shadwell and at Hackney. The New River Company declined to supply the latter place unless a certain minimum annual water rent was guaranteed to them. The source of

supply of the Shadwell Company was the Thames, and that of the Hackney Company, the Lee. The residents of South London bought much of their water from merchants who took it round in carts. The London Bridge Waterworks pumped some water to Southwark and there were other works near the church of St. Mary Overie. The Lambeth Company was started about the year 1795 and soon promised to do a roaring trade. It was energetically worked, the proprietors taking an active part in the extension of the business. At one time pipes could not be obtained quickly enough to satisfy the impatience of those desirous to be customers. The pipes then in general use were made of wood, usually of elm, and the lumen of the tube was formed by boring out the centre of a tree. The pipes fitted into one another and were fastened together by a band of iron. Such pipes are frequently dug up when the streets of London are excavated, and attention was lately called to one found in the City of London by a gentleman who happened to be passing when it was unearthed, and who promptly wrote to the *Times* concerning a portion of Roman drainage which he had lately discovered. A few specimens of these pipes have been preserved and two of them may be seen any day opposite a house situated on the south side of Jermyn-street, not far from St. James's Church. Wooden pipes were not very satisfactory, considerable leakage often took place at the joints, and it was computed that something like a fifth of the amount of water sent from the works was lost during its transit to the houses of the customers. It would be a mistake to suppose that wooden pipes were the only ones in use at the beginning of the century. Some of the mains and some of the smaller pipes also were made of lead. Wooden pipes, however, were in general use. Attempts were made at a later date to replace them by a substance called "artificial stone," but this material proved eminently unsatisfactory. ron pipes were then introduced, and although the initial expense of these was considerable they led to a great saving in the amount of water wasted, and were capable of standing high pressure without any untoward results. Very little was done at the beginning of the century in the way of water purification. Most of the companies pumped their supplies directly from the Thames and contented themselves by keeping out the grosser impurities by the use of a sort of sieve. The Chelsea Company's water was allowed to settle for a short time in their reservoirs, their customers not being sufficiently numerous to necessitate pumping every day. Of the public supplies that of the New River must have been by far the best. Some of the water came from a beautifully pure spring at Chadwell and that derived from the upper Lee was much superior to the Thames water. The New River itself was carefully guarded by stately officials who are represented in pictures as wearers of top hats and who had bound themselves by an oath to do their duty. Magistrates then took a severe view of the culprits who ventured to bathe in the river, and the offence was in the eyes of the law not a light one. The proprietors of the company and their friends made an annual survey of their property to see that everything was right; the survey occasionally occupied two days and the proprietors were wont to go down the river in a barge. It must have been a charming excursion 100 years ago. For the New River, in spite of the complete transformation of much of its landscape, is not devoid of beauty to-day.

THE AFTER-CARE ASSOCIATION.

THE work of the After-Care Association in helping poor persons discharged after recovery from asylums for the insane is deserving of greater support than it usually obtains. A home for convalescents from mental disease is a necessity, as was pointed out long ago and often by the great Earl of Shaftesbury during his prolonged office as chairman of the Lunacy Commissioners. Yet among the 240 convalescent homes on the register of the Charity Organisation Society not one appears to be specially designed and available for such inmates. The After-Care Association, by obtaining for these people, when needful, an interval of change of scene and air, by giving them grants of money and clothing, and by assisting them to obtain suitable employment, endeavours to fill a hiatus which ought not to exist. The work needs extending greatly, but this cannot be done until the necessary funds are forthcoming. The annual meeting of the association will be held in the library of Lambeth Palace on Jan. 29th, at 2.30 P.M., when the Archbishop of Canterbury will preside. All communications should be made to the secretary, Mr. H. Thornhill Roxby, Church House, Dean's Yard, Westminster, S.W., by whom contributions will be thankfully received, or they may be paid into the account of the "After-Care Association," Union Bank of London (Regent-street branch), Argyll-place, London, W. Any of our readers in search of an object for their practical benevolence can be certain that in this association they have a most worthy object, and as such it may be confidently recommended by them to laymen.

NIGHT-TERRORS IN INFANTS.

DR. ALFRED BEYRAND contributes in a recent *Thèse de Paris* (1900) an interesting clinical and psychological account of the night-terrors of children. This form of cerebral disturbance had been long recognised and in 1867 Dr. Sydney Ringer stated that there was a close analogy between night-terrors and nightmare. He adduced as common causes of both troubles bad food, excessive feeding at night, intestinal worms, and difficult dentition. Steiner (1876), however, showed from a large number of observations that an idiopathic cerebral irritation, associated probably with a transitory cerebral hyperæmia, lay at the root of this morbid psychical and sensorial disturbance. Debacker (*Thèse de Paris*, 1881) showed conclusively that vivid hallucinations of sight and of bodily feeling enter into the pathology of night-terrors and more recently Braun (1891) and Kamenski (1893) have proposed to classify this ailment in the group of neuroses which includes hysteria and neurasthenia, the actual attacks of pavor nocturnus being indications of a profound morbid nervous taint in the child. Soltmann has also shown in the "Handbuch der Kinderkrankheiten" (edited by Gerhardt, 1898) that the children who suffer from night-terrors are anæmic and present a distinct neuropathic predisposition, and that they are the offspring of families in which neuroses are found to prevail. In the present thesis Dr. Beyrand quotes a number of cases observed personally, in which it appeared that hallucinations, mainly visual, played an important part in determining the attacks. It is pointed out that in severe attacks the child screams and cries with terror, and is completely oblivious of surroundings or of the presence of parents until the terror has subsided, that the end of the crisis is generally marked by the emission of clear urine and a falling-off to sleep, and that on waking the child preserves no recollection of the horror experienced. There is no stupidity or intellectual torpor such as characterises the post-epileptic state, nor is there any convulsion or biting of the tongue. The attack is also different from somnambulism and from the nightmare following an alcoholic debauch. After passing in review the exciting causes which may provoke an attack, such as gastro-intestinal irritation from ill-digested food, or worms, teething, and infectious fevers (e.g., pneumonia and typhoid fever), Dr. Beyrand shows that the habit in France of allowing the child to sip small quantities of wine along with

the parents during the evening meal is the most fruitful cause which provokes such attacks. Lead-poisoning from toys made of caoutchouc and pottery, leaden soldiers, and the like is pointed out as a cause of night-terrors, and belladonna and aconite injudiciously administered to children suffering from whooping-cough are said to have a similarly ill effect. Children who have been frightened by nurses with tales of ghosts, dark prisons, and other terrifying things are specially liable to suffer from night-terrors. Investigations into the family history of the child reveal that in most cases the commonest factor is an alcoholic or other neurotic habit or taint in the father or mother, to which can be traced the morbid nervous condition which expresses itself in the child as night-terrors. Attacks mainly occur during the third hour of sleep, and treatment should be directed to remove all exciting causes whether internal (alimentary) or external. The bromides may be given as cerebral sedatives, and the last meal of the day should be very light and non-irritating. Education of the child should be so regulated as to abolish and suppress all morbid fears and tales provoking fear.

"TO INAUGURATE THE CENTURY."

IN the public health section of our Annus Medicus we referred last week to the probability that the year 1901 would be written down in history as a red-letter year in so far as the prevention of tuberculosis was concerned, and we drew attention more particularly to the erection of sanatoria. It is now announced that the town council of Portsmouth have honoured themselves by initiating the movement. They have determined to inaugurate the century by promoting a fund for establishing a sanatorium for phthisical patients on the southern slopes of Portsdown Hill. Portsmouth is by no means alone in its determination to erect a sanatorium, but, as far as we are aware, no other sanitary authority has made the birth of the twentieth century a basis for the movement. To some, indeed, the milestones set, partly by nature, partly by man, upon the path of time make no appeal. The passing of a century to them is no more than the passing of a year. The prolongation of the sojourn of man upon this planet concerns them not at all. Why trouble ourselves, they say in effect, with the relief of suffering, with increasing the average duration of life, with the limitation of infection? What matter?

> "You know how little while we have to stay,
> And, once departed, may return no more."

Why, therefore, let the morrow disturb us?

> "To-morrow? Why, to-morrow I may be
> Myself with yesterday's Sev'n Thousand Years."

But those who are satisfied with such philosophy are not likely to peruse these lines, and their views need occupy us no further. Life is a riddle which we possess an irresistible desire to guess. The more thinking and responsible portion of those who for a time occupy the surface of this troublous planet feel impelled to promote the growth of scientific truth, so that even if no solution of the mystery of life follow they may at least do what they conceive to be their duty by their contemporaries and also by their posterity. It is for this reason that we ask whether some concerted movement for the good and comfort of the community by the promotion of scientific research may not fittingly mark the progress of the centuries. We should be glad to see the sanitary authorities throughout the country awaken to the occasion in emulation of the Portsmouth Town Council. The idea of erecting sanatoria for the reception and treatment of consumptive patients may not in all cases commend itself, but the opportunities open to public bodies for doing sanitary good are numerous. Those who pollute our streams by their sewage might be persuaded to put an end to such pollution; the communities possessing no isolation hospital might erect one, cities where animals are slaughtered in private slaughter-houses without proper inspection might provide their inhabitants with a proper abattoir and facilities for testing their animal food. And if none of these subjects appear sufficiently sentimental for an occasion which none of us who either read or write these pages will see again, let attention be turned to the housing of the poor. Upon that platform the theologian, the philanthropist, and the sanitarian can meet to their mutual gratification. But whatever scheme may be adopted by public bodies, the opportunity afforded by the dawning century of marking a stage of human progress in some definite manner should not be lost.

AMBULANCE CLASSES AND THE LONDON SCHOOL BOARD.

AMONGST the subjects recently introduced by the School Board for London into their scheme of instruction in their evening continuation schools are those of ambulance or first aid to the injured and home nursing. In the first instance an arrangement was entered into with the St. John Ambulance Association for instruction in these subjects. The School Board for London, however, wished to have the matter entirely under their own control. They now appoint their own lecturers and examiners, their object being to obtain uniformity in the instruction given and control of the standard of pass. They have their own syllabus, compiled from those of the St. John Ambulance Association, the St. Andrews Ambulance Association, and the Aberdeen Ambulance Association, and they grant their own certificate of proficiency. The course of instruction consists of 12 lectures given alternately by a medical man appointed by the London School Board and by a school board teacher who holds the board's certificate for teachers—a certificate which is of higher grade and for which there is a more complete syllabus of instruction and a longer course. With regard to the attendances the reports show an increasing number. In 1898–1899 the attendances were for ambulance, 6800; home nursing, 2425. In 1899–1900—ambulance, 9393; home nursing, 3252. The arrangement and general supervision of the scheme have been entrusted by the board to Dr. R. J. Collie, to whom the merit of its construction is greatly due. Whether ambulance classes come under the head of elementary education is, we think, an open question, and we should like to know in what the certificated teacher gives instruction.

CUNNINGHAM *v.* THE "DAILY EXPRESS."

WE must offer our hearty congratulations to the *Daily Express* on its success in the libel action brought against it by John Bernard Cunningham. The publicity given to the trial by the daily press renders it unnecessary for us to say more than that the alleged libels imputed to the plaintiff were, according to the construction which he placed upon them, that he was putting before the public a sham and pretended cure for consumption, and that he was a quack and a charlatan, and that the jury, after hearing the plaintiff's case as set forth by himself and his witnesses aided by the skilful advocacy of Mr. Lawson Walton, Q.C., stopped the trial in the middle of the defendants' evidence and declared themselves agreed that their verdict should be for the defendants. Satisfactory as the abrupt ending of such a law-suit may be, we may be excused for regretting that the defendants' case was not completed in order that the public might be more fully warned against the kind of person who endeavours to cozen them with sham cures for disease. It is better that a lie should be contradicted and exposed than that it should be merely disbelieved. For example, Cunningham's counsel said, presumably on his instructions, that the "Medical Defence Association" had inspected the diploma of the

plaintiff and had thereupon not persisted in certain objections which had been taken to Cunningham's proceedings. Dr. A. G. Bateman, general secretary to the Medical Defence Union, has since written a letter setting out what took place between the plaintiff and his society, a letter which, needless to say, shows that this statement put in the mouth of the plaintiff's counsel was without foundation. Dr. Bateman was in court ready to give evidence had not the stopping of the case rendered his testimony, and that of any other witnesses for the defendants, unnecessary. At the same time we admit that the early stopping of a case is a more complete and emphatic vindication of the defendants' conduct than that which results after both sides have been fully heard and after the judge has summed up, while newspapers which by outspoken comment on matters of public interest run the risk of libel actions do not wish to find themselves in jeopardy longer than is absolutely necessary. For the risk run by newspapers in dealing even with the most obvious charlatans is a real one. A few words may be written on such an occasion which cannot be wholly justified and a verdict for damages and costs may have to be faced, although the plaintiff criticised may have been a person deserving the strongest censure and exposure, and although it is clear that the action of the newspaper has been taken from no other motive than to protect and to warn the public. *Crede expertis.*

THE RESIGNATION OF MR. TRIMMER.

AT the December meeting of the Council of the Royal College of Surgeons of England it was announced that Mr. Trimmer had intimated his intention of resigning the post of secretary to the College in March next when he will have completed 42 years of service. Mr. Trimmer went to the College from the War Office as assistant secretary under his friend the late Mr. Edmund Belfour in the year 1859. His powers of organisation soon proved of great use to the College in the drafting of the Regulations and the arrangement of the examination for the Licence in dental surgery which came into existence through the charter granted in that year; and, indeed, from the time he succeeded to the post of secretary in 1865 his mastery of the intricacies of the various charters and by-laws has been of immense value to the College. Those who remember the negotiations for the proposed conjoint examination scheme between the universities and the corporations will not need to be reminded of the heavy work thrown upon Mr. Trimmer, and the resource which he brought to bear on the many discussions involved by the delicate questions raised was notable. He was also largely responsible for the details of the present scheme of conjoint examinations between the College and the Royal College of Physicians of London. Mr. Trimmer has well earned his retirement, and we trust that he may have many years of life and health before him to enjoy it. Certainly the College has been fortunate in having had the advantage of his services for so many years, and whilst the Council will naturally regret to lose such an old and faithful official, they will none the less feel confident that his successor, Mr. Cowell, who has acted as assistant secretary for the past 12 years, will carry on the duties of the office with energy and ability. We understand that the Council has voted a liberal retiring pension to Mr. Trimmer.

THE BRITISH CONGRESS ON TUBERCULOSIS.

WE have received the official programme of the British Congress on Tuberculosis, which will be opened in person by H.R.H. the Prince of Wales in the Queen's Hall, London, at three o'clock in the afternoon of July 22nd, 1901. The Congress will be held from Monday, July 22nd, to Friday, July 26th. Every British colony and dependency is invited to participate by sending delegates; while the Governments of countries in Europe, Asia, and America are invited to send representative men of science, and others, who will be the distinguished guests of the Congress. Papers will be read, and clinical and pathological demonstrations will be given, detailing medical and sanitary experience in the treatment and prevention of tuberculosis throughout the world; while the museum, which is to be a special feature of the Congress, will contain pathological and bacteriological collections, charts, models, and other exhibits derived from similarly widespread sources. Authorities in this and other countries will be invited to supply documents bearing upon the historical, geographical, and statistical aspects of the subject; while as a result of the papers and discussions, practical resolutions will be formulated which will serve to indicate the public and private measures which are best adapted for the suppression of tuberculosis. The work will be divided into four sections as follows:—Section I., State and Municipal: President, Right Hon. Sir Herbert Maxwell, Bart., M.P. Section II., Medical, including Climatology and Sanatoria: President, Sir R. Douglas Powell, Bart., M.D. Section III., Pathology, including Bacteriology: President, Professor Sims Woodhead, M.D. Section IV., Veterinary (Tuberculosis in Animals): President, Sir George Brown, C.B. The chairman of the committee having charge of the Museum of Pathology, Bacteriology, and Public Health, is Professor Sims Woodhead. The secretary to this committee is Dr. W. Jobson Horne, 27, New Cavendish-street, Harley-street, W., to whom all correspondence relative to the museum should be addressed.

THE NEGLECT OF THE AGED.

AN inquest held recently at Salisbury brought to light a state of affairs which, shocking as it seemed to the coroner's jury (who censured those responsible) is by no means without parallel. An elderly woman, 79 years of age, living in a house with her daughter, another woman apparently a lodger, and her husband, who though deaf was not stated to be infirm, had died after being ill for four years and bed-ridden for 13 months. Mr. H. L. E. Wilks, who had attended her some months before, had been called in again two days before her death and had found conditions which caused him to decline to certify when asked to do so, while his evidence, given after making a post-mortem examination, showed that the deceased died in circumstances of filth, starvation, and neglect which fully justified the indignant comments of the jury, although they did not think it necessary to return a verdict of manslaughter. We further note that the foreman, with the knowledge of the persons whose conduct is under inquiry that we sometimes observe in coroners' juries, remarked that the deceased's husband could have afforded a private nurse, while there was also a district nurse at hand whose residence was known to the daughter. General practitioners whose work lies among the poor, and particularly those who carry on their profession in remote country districts, will probably be able to recall similar instances of the callousness exhibited towards the aged and infirm, not only by their younger relatives, but by the husband or wife as the case may be. These seem to resent the prolonged existence of one who is a burden and a useless expense, and if they are deterred by fear of the law from taking active measures to accelerate the end, at any rate they do nothing whatever to avert or postpone it. Such conduct towards the aged is we believe customary in some savage tribes, while the lower animals recognise no duty towards the parent or the mate which has grown weaker than its compeers. In the unhappy family at Salisbury there was, no doubt, a resentful unwillingness to incur unprofitable trouble and expense, not tempered by what we term

natural affection—the sentiment among men towards their blood relations which is rather the product of civilisation and Christianity than of nature.

"ACUTE IDIOPATHIC ŒDEMA OF THE EYELIDS."

AT the meeting of the Société Médicale des Hôpitaux of Paris on Nov. 30th, 1899, Dr. Galliard read a paper on a curious and little recognised affection, to which he gave provisionally the title of "acute idiopathic œdema of the eyelids." In 1888 Riehl recorded the following case in the *Wiener Medicinische Presse*, No. 11, p. 353. A man, aged 51 years, who had suffered from supra-orbital neuralgia and rheumatism after the death of his wife, had in 1874, for the first time, œdema of the left eyelids. Several relapses followed. In 1878 the right eyelids were affected. From that time attacks on one or other side, or on both sides, were frequent. Then his lips were affected. In 1885 he had pharyngo-laryngeal œdema and threatening asphyxia. Attacks of cutaneous œdema occurred every 10 or 12 days. There were no general symptoms. In 12 years Dr. Galliard has seen only three cases of "acute idiopathic œdema of the eyelids." The first occurred in a woman, aged 20 years, who had unilateral swelling of the eyelids with slight redness. The second case was observed in a girl, aged four and a half years. One morning without apparent cause she showed unilateral œdema of the eyelids. 24 hours later it had disappeared. There was neither cardiac nor renal disease, nor alteration in the eye—not even conjunctival congestion. Ten similar attacks took place in the next two years. After a slightly disturbed night the eyelids on one side, right or left, were enormously swollen. There was neither pain, redness, heat, nor pruritus. At the close of the day the œdema had diminished, and in from 24 to 36 hours it had disappeared. It was never bilateral or accompanied by albuminuria. The temperature was normal. The child enjoyed good health and never had urticaria. The father had arthritic tendencies and suffered frequently from hay-asthma. The third patient was a girl, aged three years, who sometimes suffered from gastro-intestinal troubles, which were never complicated with urticaria. One afternoon after walking she complained of pain in the knee. At 6 P.M. there was hydrarthrosis of the right knee with slight pain and heat. There was no pyrexia. Salicylate of soda and antipyrin were given. On the following day the swelling had diminished and on the third day it had disappeared. As the tongue was furred and as the child had lost appetite an aperient was prescribed on the fourth day. On the fifth day the general condition was good, but in the afternoon a papular erythema of the lower limbs appeared. The left limb was most affected; on the leg the papules were confluent and formed a patch which ceased abruptly at the level of the malleoli. On the dorsum of the foot was another patch separated from the upper patch by healthy skin. The leg and foot were swollen. The temperature was 102·4° F. and the child was restless. On the sixth day there was marked improvement; the temperature was normal, the swelling of the limbs had disappeared, and the red tint of the spots was replaced by a violaceous one. On the seventh day the eyelids were enormously swollen. The right eye was completely hidden, the left not quite. The œdema extended to the lower part of the forehead and root of the nose. There was no redness. The child was unrecognisable. There was neither conjunctival congestion, pain, pruritus, pyrexia, nor albuminuria. Dr. Galliard diagnosed benign œdema of rheumatic origin. On the eighth day the œdema was diminished; the right eye could be opened and the left eyelids were normal. There were some purpuric spots on the buttocks and thighs. On the ninth day the œdema had disappeared. This case differs from the preceding ones in that the œdema was not an isolated phenomenon but one of a series of "rheumatic" phenomena. The pathology of certain forms of acute œdema is very obscure. They have been ascribed to rheumatism, gout, cold, and hysteria. Until more precise knowledge is attained Dr. Galliard suggests that the œdema in his cases should be described as idiopathic. Thus, "acute idiopathic œdema of the eyelids" is a recurrent affection without prodromata, which is observed on awaking in the morning. It predominates on one side or is unilateral. From the beginning it attains such enormous proportions that it cannot be confounded with cardiac or renal affections. It is soft and devoid of redness. It is not accompanied by alterations in the eye, pruritus, or pyrexia. It lasts from 24 to 36 hours. It may be preceded, accompanied, or followed by circumscribed œdema of the cheeks, lips, limbs, genital organs, or mucous membranes. It occurs in rheumatic, arthritic, and neurotic families.

THE PROBLEM OF SEWAGE DISPOSAL.

IT must be admitted that when distinct promise is given that the enormous volume of sewage discharged from the sewers of London can be satisfactorily dealt with bacterially, then other cities and towns may confidently hope that the same process is adapted to their needs. The interesting series of practical experiments conducted during the past two years on behalf of the London County Council by Dr. F. Clowes and Dr. A. C. Houston promise to culminate in success on a large scale, at least this is the conclusion to be derived from their latest report. As may be imagined, difficulties of all kinds have been encountered, but, as in all problems, the difficulties have been exceedingly instructive, and due advantage has been taken thereof, with the result that it is now considered advisable to adopt the bacterial method of treatment of London sewage in place of chemical treatment. It is further maintained that under the conditions existing in the lower river and at the outfall this system of treatment would furnish a more satisfactory result. This is substantially the remarkable conclusion of the chemist and bacteriologist of the London County Council respectively after two years' practical study of the question. We crystallise this conclusion from the results which appear in the third report on the subject, which has just been published, relating to the experimental intermittent treatment of London crude sewage at the coke-beds at the Barking and Crossness outfalls. The first and second reports were dealt with in THE LANCET of Oct. 14th, 1899, p. 1024, and March 3rd, 1900, p. 649, respectively. In the former number we dealt with the preliminary experiments at some length in a leading article, and in the concluding paragraph of that article we wrote: "We doubt whether a more promising solution than is suggested in the conclusions of this report of the great and vexatious problem of the rational disposal of the sewage of London has yet been forthcoming." Our confidence in this mode of bringing the problem into solution is now considerably increased. The process is reduced to simplicity itself, one of the chief requirements being that the crude sewage be first allowed to deposit its sediment prior to its discharge upon the coke-bed, where it is dealt with intermittently. The experiments which have been conducted on these lines renders the conclusion reasonable "that the experimental treatment of the sewage by rough screening followed by rapid sedimentation without the previous introduction of chemicals might now be attempted on a large scale, and that by this means an effluent of much greater purity than that at present discharged might be sent into the river." It is doubtful, however, whether the effluent, although chemically pure, is in

actuality above bacteriological suspicion of danger. But, as Dr. Houston remarks, a process which leads to the solution of the great mass of suspended matters in the raw sewage, which effects a striking reduction in the amount of putrescible matters, which avoids the use of chemicals and the accumulation of offensive sludge, which yields an apparently non-putrescible effluent, and which is at the same time practicable, is one which presents such singular advantages over chemical treatment, that it would be idle to deny its value or to attempt to minimise its usefulness simply because it falls short of a standard of absolute perfection. This is perhaps a rosy view, but these conclusions are based, in our opinion, on one of the best experimental investigations that has ever been carried out. We strongly recommend a careful perusal and study of this exceedingly interesting and valuable report to all concerned in this great question of sewage disposal.

THE PRINCESS OF WALES'S APPEAL.

PERHAPS no one can better appreciate the sore need of the families of the poor when the bread-winner is for some reason or other unable to render the aid which is expected of him than the medical man, and it is with feelings of the greatest sympathy that we refer to the appeal which the Princess of Wales, as President of the Soldiers' and Sailors' Families Association, has just issued. In a brief account of the work which the association is endeavouring to carry out Her Royal Highness states that since the commencement of the war over £510,000 have been directly entrusted to the care of the association, supplemented by £190,000 subscribed for wives and families to the Mansion House Fund, and £50,000 received from the Lord Mayor of London's "Discretionary" Fund. The whole of this sum, amounting to £750,000, distributed through the voluntary services of 11,000 ladies and gentlemen, members of the association, is now nearly expended. The last returns show that over 80,000 families have been relieved, but the number of cases do not diminish to the extent which might be expected owing to the fact that local funds have become exhausted and have transferred their cases to the association. At the present time not less than £50,000 per month are being given in relief. The aim of the association has been to maintain the families in the same position as they were when their supporters were at home. Assistance has also been given to aged fathers and mothers who relied upon their sons for support previously to rejoining the colours. "Without further funds," says Her Royal Highness, "these homes must be broken up and all that we have been doing for the last 12 months will be undone." The Lord Mayor of London has consented to receive subscriptions sent to the Mansion House for this object, and the Princess of Wales invites the coöperation of lords lieutenant of counties, and of lord mayors, provosts, and mayors throughout the kingdom to help her in the same way. Subscriptions will also be received by the local branches in each county and by the treasurer, Colonel James Gildea, C.B., at 23, Queen Anne's-gate, Westminster, S.W. Surely the appeal of the Princess will not be in vain.

WE announce with great regret the death of Dr. John Baptiste Potter, obstetric physician to the Westminster Hospital, which occurred on Sunday last, Dec. 30th, 1900. We shall publish shortly a fuller obituary notice.

LORD ROBERTS, who arrived at Cowes on Wednesday morning last, was graciously received on the same day at Osborne by Her Majesty the Queen. The whole nation is gratified by learning that the gallant Field Marshal has been created an earl and has also been appointed a Knight of the Order of the Garter.

"CLUCKS" AND "CLICKS."

BY W. AINSLIE HOLLIS, M.A., M.D. CANTAB., F.R.C.P. LOND.

AS the days of Boer supremacy in South Africa are numbered, it may be thought not uninteresting to consider, before it is too late, another residual product of the veldt whose days are also numbered so soon as English board schools are established in the Transvaal Colony and the Orange River Colony. I allude to the lingual "click" of Kaffraria and the surrounding districts. There are evidences, to which I shall hereafter briefly refer, that this suctional note was at one time widely distributed in speech among the nations of mankind. My present purpose, however, is to consider the physiology of an expressive sound—or, more correctly, series of sounds, for there are several modifications of the "click" still extant—and to draw attention to its close relationship to similar notes still in use as calls among some of the lower animals.

In general terms the "click" may be said to be produced by first pressing the tip, edges, and a part of the dorsum of the tongue against the hard palate, exhausting the air from the cavity so formed, and then, mainly by the action of the muscles attached to the styloid process and the hyoid bone, forcibly withdrawing the tongue from the position it has assumed. This operation allows the air to re-enter the partial vacuum and a "click" is the result. As regards the "clicks" at present in use amongst the Ngoni (Zulu), Xosa-Kaffir, and other of the Bantu tribes, European writers, such as Torrend, Elmslie, and Roberts, agree in dividing them into three varieties—namely, the dental, the palatal, and the lateral. The two first are chiefly distinguishable from each other by a reference to the position of the tongue-tip when the sound is made. In the former case the tip is placed close to the roots of the upper incisors; in the second case the tip is placed considerably farther back. The lateral "click"—which, by the bye, is still to be heard from the mouths of English drivers—is really a modification of the second form of note wherein the edge of the tongue is first raised for the re-admission of air instead of the tip. So we shall find that the Zulu "clicks" may be arranged physiologically under two headings—the anterior palatal and the posterior palatal, according to the location of the tongue-tip whilst the sound is produced.

If we now pass to the other side of the world, to the home of the Dakota Indians, we learn through the voluminous work of the Ethnological Section of the United States Survey of the Rocky Mountains that these tribes also possess, or until recently possessed, a language in which no fewer than four "clicks" were recognised. Phonetically these "clicks" differ from those of South Africa, in so far as each "click" represents a definite out-breathed consonantal sound modified by the suctional manner of its production. Yet, physiologically, the method of uttering these notes is very similar; and from what the writers of the dictionary state we may assume that the *p* and *t* "clicks" of Dakota were anterior palatal, and that the *c* and *k* "clicks" were posterior palatal. In other words, we find in each hemisphere of the world tribes of men who have retained in their speech these remarkable suctional notes, despite the fact that the rest of their language was composed of out-breathed syllables.

Man, so far as I know, is the only mammal which uses a suctional note. Curiously enough, certain lizards of the South African veldt, the so-called "clucking sand lizards" do, as their name suggests, utter a "cluck," which in their case is probably a sex-call. At home, however, in every farmyard there are endless opportunities of observing an avian "cluck." The "clocking" of a broody hen—as old John Ray, the seventeenth-century naturalist, called the sound whereby the domestic fowl summons its family to a feast—is familiar to us all. Certain peculiarities touching the nature of this avian cluck have led me to conjecture that it and the human "click" are both descendants of a common ancestral "cluck." The peculiarities in question group themselves for consideration under various headings—namely, the kind of sound, its structural cause, and finally its significance as a call. If we compare the "cluck" in this manner with the human "click" the striking affinities displayed in each instance will, I believe, justify the above

surmise. Unfortunately I have been as yet unable to investigate the "cluck" of the lizard to which I have referred. I have, in effect, restricted this part of the inquiry to the hen's "cluck."

To begin with the phonetic nature of the note. If a clucking hen surrounded by her brood of chickens be quietly observed three facts may be noted. 1. The sound produced is a dissyllable, a "culuck" and not a "cluck." This observation, as we shall learn subsequently, is of interest. 2. The beak is closed when the sound is made. 3. The hyoid bone with the larynx ascends at the commencement of the note to sink again immediately afterwards. As regards the structures which bring about these results a few words may now be said, and in so doing I must apologise for describing the hyoglossal apparatus of the common fowl. From an observation published in one of the most recent text-books on birds it seems, however, that there is a very general idea abroad that the tongue has nothing to do with the utterance of all notes emitted by birds, with one possible exception, the sounds taught to parrots. Against this sweeping statement I must protest, and I feel that I can best do so by describing briefly the beautiful mechanism in the fowl's mouth and throat by which the cluck is undoubtedly produced. The somewhat V-shaped os hyoides has its body prolonged forwards in the form of a spur, which is embedded in the root of the tongue. At its distal extremity this spur ends in a hinge-joint about half an inch from the tongue's tip. A further spicule of cartilage extending mesially forwards to within an eighth of an inch of the tip and presumably bearing the horny covering of the under-surface of the fore-tongue, completes the joint. The joint is apparently furnished completely with bursæ, synovial cavity, and so on. By two cylindrical muscles arising from the greater cornua and terminating in two long tendons, one inserted on either side of the under-surface of the fore-tongue, this part of the organ can be bent downwards independently of the rest of the tongue. When the hyoid apparatus is moved upwards the tongue, which usually rests in a cavity between the rami of the lower jaw, is also raised, pressing against the cleft palate. This movement practically closes the resonant oral cavity behind. When the hyoid bone is subsequently lowered the back part of the tongue must immediately descend with it, and in so doing it unseals a part of the palate. Owing, however, to the joint in the mid-tongue, the fore portion can for awhile still retain its position in proximity to the palate until the further descent of the hyoid occasions its displacement also. And so it is apparently brought about that the chicken's tongue shall leave the roof of the mouth in two detachments and that their removal shall coincide with the descent of the hyoid bone and the emission of the dissyllabic "culuck" of a "broody hen."

When the precursors of the Indo-Germanic nations decided to give up the primitive "click" for out-breathed equivalents that note had doubtless already been separated into the two great "click" families, the anterior palatal and the posterior palatal. This sub-division, as we may conjecture from the hen's anatomy, was probably in the first instance the direct result of structural necessities. When, after the lapse of geological ages, organic difficulties had been overcome and the mobile human tongue had devised fresh variations of the suctional note, these varieties, with their out-breathed equivalents, still fell naturally under two headings, largely dependent upon the distance of the tongue-tip from the upper incisors. Accordingly we recognise in the English "cluck," "click," "clock" and the German *glucken* an out-breathed equivalent of an ancient front "click"; whilst such words as the English "crack," the German *krachen*, and the French *crique*, *gripper*, hide the descendants of a post-palatal "click." An investigation of the modern "clicks" and their Indo-Germanic representatives strengthens this conjecture, as I shall briefly show. It will be noticed also that this inquiry indirectly confirms the hypothesis that the avian "cluck" and the human "click" have had a common origin.

Whether the sand lizards "cluck" whilst they excavate their burrows is more than I can assert. Every farm-labourer, however, will admit a close association between clucking and scratching the soil in the case of the domestic fowl. In the language of Dakota (of which, by the way, a dictionary has been compiled filling a thick quarto volume) precisely six words begin with a *c* "click," a few more begin with the *k* "click." Amongst that small number of words, a considerable percentage of which are conjunctions or other parts of speech, we nevertheless find two verbs, *ca*, *ke*, signifying "to dig," one, *kéga*, "to scrape," and one derivative again, *kes-ké-za*, "trodden down, smooth"; the final word containing two *k* "clicks." This close association between the posterior "click" and scraping the soil is not confined to a nation of Red Indians, the Old English *cratch*, the Old Dutch *kratsen*, the German *kratzen* ("to scratch"), the French *griffer*, the German *graben*, and the English to "grub," or dig, probably conceal in the initial *cr*, *kr*. and *gr*, the out-breathed equivalent of the suctional note. If we turn to Zululand this relationship may seem apparently absent. It is traceable, however, although the mental connexion between the note produced and its significance is not the same in the two cases. Whilst in Dakota the operation of scraping the soil appears to have been uppermost in the mind of the primitive savage whenever he uttered the hinder "click," the ancient Xosa-Kaffir must have looked rather at the mechanism for producing this result—at the hooks and claws arming the limbs of men and animals when they harried the surface of the ground. To his simple mind the *Aasvogel* of the veldt (Zulu *inqe*,[1] English "griffin," French *griffon*), was the embodiment of hooks and eyes, and its name was consequently the casket for one "click" or more. (Some tribes, I understand, introduce two "clicks" into this word.) Here again the Indo-Germanic group of tongues assist, for we find the Old English *crycc*, the English "crutch," "crook," and the French *croc*, represented in the Zulu *ibaxa*, a word containing a lateral "click."

I must not, however, occupy these pages with a philological disquisition. I shall conclude, therefore, with a few examples of the anterior "click" and its English equivalents. Such words as "clip" (Zulu *ncotyoba*), "clasp" (Zulu *peca*), "cloudless" (Zulu *cvebile*), to be "clear" (Zulu *cansa*), to "close" the eyes, the mouth, the door respectively (Zulu *cima*, *cuta*, *vingca*), all have an anterior click; whilst the Dakota *tin-za*, "stiff" (as mud), *po*, "fog," "mist," have representatives in English "clay" and "cloud," a further support to the argument that the Indo-Germanic *cl* is the out-breathed equivalent of a front "click."

REFLECTIONS ON THERAPEUTICS.

BY HARRY CAMPBELL, M.D., B.S., F.R.C.P. LOND.,
PHYSICIAN TO THE NORTH-WEST LONDON HOSPITAL AND TO THE WEST END HOSPITAL FOR DISEASES OF THE NERVOUS SYSTEM.

I.

THE VIS MEDICATRIX NATURÆ; THE LIMITATIONS OF THERAPEUTICS.

ONE of the first lessons the young physician has to learn—too many never learn it at all—is the limitation set by Nature upon his therapeutic measures. He has to grasp this primal fact—that she herself is the great physician and that compared with the vis medicatrix naturæ his powers are feeble and insignificant. The potency of the vis medicatrix, the importance of relying upon it chiefly, allowing it full scope, and not for ever, by fussy interference, impeding its beneficent action, was brought home to me early in my medical career. It was forced upon me by the following analogical argument which, though open to criticism, as argument by analogy is bound to be, serves the purpose I have in view. The argument is briefly this: we may regard disease as a natural variation, as a variation from the normal, and just as all natural variations tend to revert to the normal, so also does disease. This brings the vis medicatrix into line with the phenomena of reversion.

Now there are two kinds of reversion. There is, first, reversion as commonly understood, or developmental reversion, that, namely, in which the organism does not develop on the ordinary lines, and of this variety I have nothing to say here. Secondly, there is that form of reversion in which the organism, having partly or completely developed, retrogresses and thereby displays lost characters belonging to past ancestors; it is to this second form that I wish to direct attention in this place. One of the most striking instances of it is afforded by acromegaly, most of the

[1] The Zulu "clicks" are usually rendered by the letters *c*, *q*, and *x*; these letters are merely symbols, and the "clicks" have no sonorous connexion with them. The *q* represents the posterior palatal "click."

characters of which, as I have shown elsewhere,[1] are anthropoidal—i.e., belong to the man-like apes. As another instance, and one more useful for my purpose than acromegaly, let us take the case of a cultivated plant allowed to grow wild—the cabbage, for example. Under such conditions it tends to revert to the condition of its wild congener. In short, when placed under primitive conditions it tends to revert to a more primitive and stable state. Similarly, in regard to disease: disease is a variation from the normal stable state and the organism shows a tendency to revert to that normal stable state when placed under normal, simple conditions of warmth, fresh air, and so forth. In each case the pendulum which has swung from the position of equilibrium tends to settle back in it, this backward swing in the case of disease being the work of the vis medicatrix.

The vis medicatrix a highly complex process.—But though it is easy enough to refer the vis medicatrix to the principle of reversion, when we come to examine carefully into the process we find that it is not by any means a simple one, but, on the contrary, inconceivably complex, a process in which the organism puts forth supreme efforts, bringing into play numerous mechanisms which have been laboriously evolved through the ages and in the evolution of which as much care has been bestowed, if I may speak teleologically, as in the evolution of the many other physiological attributes belonging to the organism—circulatory, respiratory, digestive, or what not. In other words, Nature is infinitely wiser in medicine and surgery (but especially in the former) than we are wont to conceive; she has a complete system of her own, and compared with her share in the healing process ours is insignificant in the extreme. If once we get thoroughly imbued with this idea, and if we realise how crude and impotent are even our most delicate and successful methods compared with the refinement and efficiency of hers, we shall be the more inclined to trust to her wonderful healing power, always seeking to give it the fullest possible scope, and scrupulously abstaining from lightly employing any means of our own, lest unwittingly we interfere with her work and only hinder where we hoped to help.

The surgeon is much less likely to err in this respect than the physician. He removes a piece of dead bone, pulls out a bad tooth, opens an abscess, and in all this he is acting in perfect conformity with Nature's own methods, only doing quickly what she must perforce do slowly. But though in such cases the results are obvious and unmistakeable, how small and insignificant is the surgeon's share in them compared with Nature's! Take the case of a tooth extraction: great good may be done by this operation which is as direct and rapid as it is effective, and yet even in such a case, where all the credit for skill seems to belong to the surgeon and little or none to the organism, when we come to look deeper we find the actual facts to be far otherwise. The surgeon's share in the result begins and ends with the removal by gross mechanical means of the source of irritation. To Nature is assigned the far more difficult and momentous task of repairing the injury actually inflicted by the operator himself in his effort at relief, and did she fail in her part the patient would assuredly die, in spite of the removal of the irritant, the original cause of trouble. For the injury is a violent one; bone is riven, muscle, nerve, and connective tissue are rent, vessels are torn, blood is poured out in profusion—all is chaos and confusion; but under the magic of Nature's ceaseless working out of that chaos and confusion order is unerringly restored, and that with marvellous rapidity. Armies of cells are engaged in the work of repair, and silently, slowly, with an adaptation of means to end a thousand times more exquisite than the utmost refinement of skill on the part of the surgeon, whose wrench, however deft, is coarse and rough in the extreme compared with Nature's imperceptible methods, the shattered tissues are repaired and an architecture is built up again, infinitely more delicate and more highly elaborated than anything that human ingenuity could devise. And all this is done so unobtrusively, unfalteringly, and painlessly that we accept the ultimate result as a matter of course, giving little or no thought to the means by which it has been effected.

But if even in surgery the vis medicatrix plays so large a part, how much larger is that which it plays in medicine? Here in the vast majority of cases Nature effects a cure unaided, and even in those instances in which the physician does good his share in the healing process is but small. Take valvular disease of the heart, on the treatment of which we are wont to pride ourselves, and consider the accurate readjustments which take place as regards hypertrophy and dilatation of the cardiac chambers and changes in the valves themselves.[2] And so it is with every disease which the physician is called upon to treat—Nature puts into operation special methods of cure of her own. There is, so to speak, a great physician resident in each organism—a body physician, in fact—who treats every illness in a special way, and we must beware that we in no way interfere with that all-wise healer nor arrogantly seek to teach her a lesson; rather let us work with her on her own lines and with open mind humbly learn of her.

This is not the place to attempt a study of these Nature-methods of cure: I am merely seeking to emphasise an all-important principle, and it will be sufficient if I call to mind what we have recently learned concerning the antitoxins. And what does this amount to? What but that the organism actually manufactures and administers medicine to itself! And elsewhere[3] I have sought to show that, apart altogether from the antitoxins, the blood and tissues contain numerous substances which play the part of drugs—"drug-substances" I have termed them—and that many of those metabolic by-products which we have been in the habit of looking upon as useless, or actually poisonous, exert an important influence in modifying functions, having on the organism, in fact, similar effects to drugs artificially administered.

All the great physicians of our time have grasped the fact—and it is more than half the secret of their greatness—that Nature is the chief healer and that many diseases are recovered from quite as readily without treatment as with it. This is why it is generally found that as the physician grows older his methods become simpler, that he abandons one drug and method after another, and finally settles down into a plan of treatment which we can best characterise as based on the slightest possible interference with Nature. The young physician, crammed with theory and all the "ologies," not unnaturally attempts to put into practice the knowledge he has laboriously acquired, and but too often it is to the great detriment of his patients. Over-assiduous, or rather over-officious, with the officiousness of inexperienced zeal, he must for ever be intermeddling, seeking to force Nature's hand rather than, as he should, to supplement her work. He is the helmsman—so he believes—of a storm-driven ship in dangerous waters and his the task to steer clear of the rocks and shallows. Accordingly daily and even hourly he worries his poor patient with treatment of some kind. If the temperature goes up he must reduce it; there is diarrhœa, he must stop it; or profuse sweating, this also must be checked. Eventually the patient recovers, and the physician fondly deludes himself that the recovery is due to his skill, whereas in all probability it would have been as quick, perhaps quicker, if after a few simple directions the patient had been simply left to the ministrations of a good, sensible nurse. I could cite numerous cases in illustration of this truth. The one which I shall quote, though taken from the sphere of obstetrics, will answer my purpose as well as any.

When I was on a visit to the country some years ago a local practitioner called on me and asked if I could see a midwifery case with him. I explained that though I was not altogether ignorant of obstetrics as taught in the books, I was not a practical obstetrician; but as, in spite of my disclaimer, he continued urgent, I consented to go, on the understanding, however, that I should not interfere with his methods or accept any responsibility in the case. It was a first pregnancy, and we both agreed that the presentation was a breech. As the woman had been in labour some time he decided that a leg ought to be brought down. This view did not altogether commend itself to me, for there was no evidence of obstruction of any kind and careful measurements showed the pelvis to be normal, the soft parts appearing so also. However, my colleague was confident as to the correctness of the procedure, and as he had had a large experience I deferred to his judgment. After a good deal of effort one leg was got down, and shortly afterwards the second. Whereupon—and before I had time to hinder him—my companion seized both the legs and forcibly pulled

[1] The Scalpel, January and February, 1896.

[2] I have elsewhere shown that in obstruction of the cardiac orifices these latter and the passages leading up to them are so modified as to facilitate to the utmost degree possible the flow of blood through them. (THE LANCET, March 10th, 1894, p. 594).

[3] "The Craving for Stimulants," THE LANCET, Oct. 21st, 1899, p. 1091.

upon them, with the inevitable result that the arms got extended over the head, and, the latter likewise extending, the chin hitched against the pelvic brim and became fixed there. There was little difficulty in delivering the arms, but the head, in spite of powerful traction made upon the body, stuck firm. The practitioner thereupon proceeded to decapitate. I suggested, but without avail, that this might not be an altogether wise procedure, since it would deprive us of a means whereby traction could be made. After the operation had lasted about half an hour the operator was quite exhausted, large beads of perspiration standing on his forehead, and I relieved him, making occasional attempts to deliver the head by lifting the child's body on to the mother's abdomen, &c. (it was an occipito-anterior case) and eventually succeeding. When the head was delivered what was my dismay to find the practitioner pulling on the cord for all he was worth. Matters now assumed a serious aspect; hæmorrhage was profuse and the woman fell into a faint. Finally, however, to cut the matter short, we succeeded in getting the uterus to contract firmly and the patient ultimately made a perfect recovery. As I was bidding him good-bye that night that medical man said to me: "Well, what do you say to the case? I know; you think that if we had left the patient entirely alone everything would have gone on all right." I nodded, and we parted. Now, if ever there was an instance of meddlesome interference, and that of the worst sort, this was surely it. The wrongness of the methods adopted is self-evident, flagrant, all the accepted canons of obstetrics being deliberately set at nought; but I make so bold as to say that we physicians not infrequently subject our patients to treatment every whit as pernicious, though, because it does not comprise mechanical operations the effect of which can be accurately gauged, but works insidiously and imperceptibly, the harm done is not so readily appraised and brought home to us as in cases like that just cited. Let us boldly acknowledge the humbling truth that patients often get well, as in the above case, in spite of our treatment not because of it, and let me urge the younger members of our profession to endeavour to realise early in their career the limitations of therapeutics, and not to wait till many years of hazardous experiment and painful failure have burnt the fact into their consciousness.

These limitations are, as already hinted, far greater for the physician than for the surgeon. A surgeon in extensive practice saves hundreds of lives and relieves untold distress by his direct personal intervention, and every day sees the physician more dependent upon his aid. The latter finds himself continually made most painfully aware of his own impotence and his dependence upon Nature and the knife, and never more so than in cases, like perforated ulcer or intestinal obstruction, where, helpless himself to do more than indicate the nature of the trouble, he has to leave it to the surgeon's skill to rescue the patient from imminent death. I do not make these remarks to belittle the physician—the very difficulties which beset him make his efforts so much the more arduous, so much the more admirable—but solely that we may recognise our limitations and be under no delusions as to our powers.

It is in the treatment of acute disorders that we feel, or should feel, our limitations most. The wisest treatment for most of them can be best summed up in the dictum; "Nature and the nurse."

Take the case of acute croupous pneumonia. The fact that so many different treatments are employed in this disease at once casts doubt upon the utility of any of them, and I am persuaded that we seldom cut short the attack or save life by adopting any measures beyond careful nursing. The cure, if effected at all, is effected by the great physician within, who has resorted to special means for destroying the pneumococcus, for carrying off the inflammatory products, for eliminating the toxins (as exemplified by the "critical evacuations"), and the like. I do not say that we may not sometimes help the vis medicatrix naturæ—far from it—and we may one day discover an antitoxin for pneumonia as efficacious as that employed in diphtheria, or some drug which shall be as effective as mercury or iodide of potassium in syphilis; but at present we have discovered neither the one nor the other. I am even prepared to admit that we may occasionally—though I believe it is very occasionally—save life by judicious bleeding, by cardiac stimulants, by oxygen inhalations; ice to the chest also may do good, chloral may help in delirium, and so forth. Nevertheless, we shall do well in all simple, uncomplicated cases of pneumonia if we content ourselves by merely relieving distressing symptoms, and I would only sanction specific treatment in those exceptional cases where it seems very definitely to be called for. My advice in this, and indeed in most diseases, is, "When in doubt leave all to Nature, and do nothing." As an instance of harmful interference I may refer to a hospital patient of mine in whom the critical fall of temperature was marked by a profuse diarrhœa. This the house physician checked, with the result that the temperature rose again to fall when the astringent mixture was withheld.

The second acute disease which I will mention is rheumatic fever. This, like pneumonia, is a germ disease, and we are as powerless to kill the germ of the one as of the other. I am doubtful whether our treatment for this disease is any better now than it was fifty years ago, or for the matter of that a thousand years ago, and whether, with the exception of those rare cases of hyperpyrexia where life can occasionally be saved by the bath, we have learned to diminish the mortality from this dread scourge of the human race by even 1 per cent. It was thought when salicylate of soda was first employed in rheumatic fever that the malady was to be henceforth robbed of its worst terrors. But what after 20 years' experience do we find? That physicians are divided into two opposing camps—the one holding that it is right and proper to employ the drug; the other that the remedy is in itself baneful and actually aggravates the morbid processes though it relieves the pain. I think for the purposes of my argument that we may fairly set the one camp against the other and regard the battle as a drawn one, which places us in much the same position as regards the efficacy of our treatment of the disease as we were 20 years ago. And what was the verdict then, and before then? The statistics of Gull and Sutton show that the patients did as well on peppermint water as on anything else.

I next come to typhoid fever. With Sir William Jenner's discovery the physician leaped at once, in the matter of the treatment of this complaint, from darkness into light. Sir William Jenner taught us the necessity of careful dieting and rest. Add to this the reduction of hyperpyrexia by suitable means and an occasional dose of calomel perhaps, and there is little more to be done in nine cases out of ten. I find that my typhoid fever mortality well bears comparison with that of other physicians, and the guiding principle of my treatment is, after taking due precautions, to leave the cure to Nature. I have satisfied myself that no drug has a specific effect

Finally, I will instance acute nephritis. To read the books one would fancy that we had made enormous strides in the treatment of this affection within recent years. I can only speak as I see, and my experience is that we have little or no control over it. Nephritis is presumably due to some toxin or toxins passing through the kidneys and exciting them into inflammation. But whence their origin, and how to prevent their production? Practically all we can do is to diminish the work of the diseased organs by limiting diet and getting the skin and bowels to act. No drug has the slightest effect on the morbid process. We may sometimes pull a patient through an attack of uræmia by bleeding, but after all is said and done the treatment of acute nephritis essentially consists of "Nature and the nurse."

I end, then, as I began. Our powers are limited, nor can we hope by even the most enlightened therapeutic measures to usurp the great prerogative of healing which Nature has so jealously reserved to herself. She is sovereign, and all that we can aspire to is to be her ready henchmen, alert to follow the slightest leadings she vouchsafes us, as we pursue our unwearying search after wider and more intimate knowledge of the laws by which she works, and through which alone we can participate in her victories over disease and death.

ADDENBROOKE'S HOSPITAL, CAMBRIDGE.—Mr. A. Peckover, Lord Lieutenant of Cambridgeshire and president of this hospital, has contributed another £1000 to its funds to commemorate the beginning of the new century.

DUNDEE INFIRMARY.—Sir Wm. Ogilvy Dalgleish, of Errol Park, who on several previous occasions has been a liberal donor, has again manifested his interest in this institution by announcing his intention to bear the cost, estimated at between £500 and £600, of structural alterations, additions, and improvements to the eye ward.

THE LANCET

Analytical Commission

ON THE

SCOPE OF ARSENICAL CONTAMINATION TRACEABLE TO IMPURE SULPHURIC ACID.

THE recently discovered contamination of beer with arsenic has opened a vista of interesting speculation as to what articles of food or drugs or materials in common use are exposed to the same risk of contamination. Arsenic has been found in a goodly number of things hitherto in which its presence can hardly be regarded as accidental. Arsenic in wall-papers, for example, was used as a colouring agent, and the poisonous metal was found in green candle-shades, in green Christmas candles, in carpets, in book-bindings, and in a number of other articles in which its green was employed as a necessary part of the colouring agent. It soon appeared that arsenical pigments were the source of grave danger, and in response to repeated demands in THE LANCET and other journals arsenic was abandoned as a colouring agent, at least in those materials—such as wall-papers—which are likely to have an injurious effect upon health. Traces of arsenic have been from time to time reported in certain dyed fabrics. The arsenic present was attributed to its use in the preparation of the dyes and the quantity found was invariably small. This accidental occurrence of arsenic in dress and other materials, is, however, of interest in relation to the present panic which exists as to the widespread possibility of arsenic being present in beer. In beer, arsenic is obviously an accidental impurity. As is now well known, the arsenic had its origin in the impure oil of vitriol used for preparing the sugar for brewing purposes. It is remarkable that even in view of this origin the quantity of arsenic which found its way into beer should be, relatively speaking, large, especially when we consider that the sulphuric acid employed for the conversion of starch into glucose or cane sugar into invert sugar is used in a diluted state. One point, however, which appears to have escaped notice so far, is that arsenic forms a definite compound with sulphuric acid which is decomposed on the addition of water into white arsenic and sulphuric acid. We know of an instance where crystals of white arsenic had deposited in considerable quantity in a carboy which had contained commercial oil of vitriol and to which water had been added.

The extent to which oil of vitriol is used in the manufacturing processes of this country is enormous. It has indeed been said that our commercial prosperity could be accurately gauged by the amount of sulphuric acid consumed in this country. The use of sulphuric acid is associated with the production in many instances of articles of food, or at any rate of substances which are taken into the human economy, while materials of familiar daily use are at some step or other in touch with sulphuric acid in the course of their elaboration. Malt substitutes used for brewing beer are perhaps the best examples of substitutes used ultimately for human consumption which are prepared by the agency of sulphuric acid. The function of malt diastase is to convert the starch of the barley into malt sugar ready for fermentation. Sulphuric acid is more commonly employed for the same purpose—converting cheap starches or cane sugar into the fermentable invert sugar. It happens that sulphuric acid is liable to contain arsenic from the pyrites from which the acid is produced, and thus arsenic has found its way into substituted sugars and so into beer. Apparently, the fact that sulphuric acid is used in the production of so many articles of everyday use, including food and drugs, is not very generally recognised. Not many months ago arsenic was found in an effervescent powder largely composed of phosphate of soda, and the presence of the poison was traced to the use of sulphuric acid in the preparation of the phosphate crystals. It must be realised, however, that arsenic may occur in a number of materials in the preparation of which at some time or other sulphuric acid is concerned. Such are, for example, boric acid, oleic acid, soap, blacking, glycerine, citric acid, tartaric acid, salicylic acid, Glauber's salts, alum, effervescing salts, commercial manures, and so on. All these substances may at some time or other in the course of preparation be in contact with sulphuric acid, if, indeed, the final product does not actually contain the acid itself. It follows that arsenic may occur in tobacco, including cigars and cigarettes, jams, sweetmeats, lemonade, liqueurs, and many effervescing medicinal salts. Tobacco may contain arsenic from the glucose or glycerine used as a sweetening agent. Jams, sweetmeats, lemonade, and liqueurs may contain arsenic similarly from glucose possibly used in their manufacture. Most blacking is made with, and generally contains, free sulphuric acid. Citric acid and tartaric acid are made by decomposing the lime salts obtained from lemon-juice and grape-juice respectively with sulphuric acid. Boric acid and salicylic acid are obtained in a similar way. Glauber's salts, or sulphate of soda, a popular and cheap form of purgative, are obtained by acting upon common salt or nitre with sulphuric acid. Alum is produced by acting on clay with sulphuric acid. Oleic acid is prepared also from fats, frequently by the agency of sulphuric acid. In a similar way the presence, if any, of arsenic in soap might be traced to the sulphuric acid employed at some time or other in the course of manufacture. Commercial manures and fertilisers are almost invariably made by acting upon bone ash with sulphuric acid, thus rendering the phosphoric acid soluble and available for plant assimilation. These speculations have led to the present inquiry, and our Commissioners have during the past few weeks procured a number of articles of the above type and have submitted them to careful examination with a view to deciding whether or not arsenic occurred in them.

Tobacco, Cigars, and Cigarettes.

It is well known that glycerine or glucose is added to tobacco to give substance to the cut leaf. We examined a number of samples of sweetened tobacco but without getting the slightest indication of arsenic.

Blacking.

Arsenic was found in mere traces only in blacking. In any case the presence of arsenic in small amount would not matter much in blacking.

Sweetmeats.

A number of sweetmeats were examined but not a trace of arsenic could be found in them. Similarly several fruit jams when examined for arsenic gave negative results.

Lemonade.

No arsenic was found in several samples.

Liqueurs.

Sugar, of course, is a large constituent of liqueurs, and it might be glucose. Of two liqueurs examined we could not find a trace of arsenic in either sample.

"Lemon Crystals."

These are largely employed for the preparation of an acidulated beverage. We could find absolutely no arsenic in the samples examined. Arsenic in lemon crystals might exist in the sugar, tartaric acid, or citric acid.

Acids.

Specimens of citric acid and tartaric acid as ordinarily sold in the shops were likewise submitted to examination for arsenic, but in no case could the slightest trace of arsenic be found.

Soap and Oleic Acid.

Specimens of common bar soap were found to contain just a trace of arsenic, but no arsenic was found in oleic acid.

Effervescing Salts.

Specimens of natural Carlsbad salts were obtained, but in no instance was arsenic found in them. In two specimens of artificial Carlsbad salts arsenic was definitely discovered in one. It may be referred probably to the use of common sulphate of soda or Glauber's salts. In the samples of effervescing citrate of magnesia examined no arsenic was found.

Glauber's Salts.

Distinct evidence of arsenic was found in the crystals examined.

Artificial Manures.

Arsenic in very distinct quantity was invariably found in the specimens of artificial manure examined. This is hardly surprising since artificial manures commonly consist of the so-called superphosphate or soluble phosphate of lime made

by adding common oil of vitriol to bone ash. The question has been raised before as to the possibility of these fertilisers infecting plants or roots with the arsenic contained in them. We refer to this portion of the inquiry in particular because recently it has been freely stated that arsenic has been found in malt and hops and in beer brewed entirely from malt and hops. It is possible that the arsenic thus said to be found may have another origin, but the fact remains that plants do assimilate arsenic and that artificial manures are frequently arsenical, and a very wide field for inquiry in opened thereby. Some years ago Dr. Edmund Davy positively stated that arsenic as it exists in artificial manures is taken up by plants growing where these manures have been applied. He found cabbages and turnips taken from fields manured with superphosphate giving unmistakeable evidence of being arseniated. In some experiments conducted by the late Professor Tuson of the Royal Veterinary College the results were such as to confirm the assertion of Dr. Davy. Also a French investigator came to the same conclusion. Professor Tuson regarded these facts as having some important bearing, for as arsenic is well known to accumulate in soils, the effects after some time might possibly be that vegetables raised on those fields continuously so manured would ultimately be found to contain a proportion of arsenic able to exercise an injurious effect on the health of men and animals. It would be rash to assert that the arsenic which has been found recently in malt and hops owed its origin to this source, but the point is well worth attention at the present juncture that artificial manures are often rich in arsenic and that plants will easily assimilate this poison.

It will be seen that the foregoing results are reassuring. For in spite of the fact that the substances which have been examined are most probably at some time or other in the course of their preparation submitted to the action of sulphuric acid, yet arsenic as an accidental impurity was, on the whole, not found to be present even in infinitesimal quantity. If sulphuric acid had been employed at all in the instances quoted it was pure. Certain substances did contain arsenic, although in unimportant quantity. The inquiry teaches, however, that as these things are liable to contain this poisonous impurity a careful watch should be kept over them. This is provided for in the Food and Drugs Act, which might usefully be turned to the examination of such articles of food and drugs as are herein indicated. The danger involved by the use of sulphuric acid in the manufacture of all compounds intended for human consumption can be obviously avoided by the use of pure sulphuric acid, and some rigid precautions are necessary which shall ensure the supply of arsenic-free sulphuric acid for these special purposes.

We may add, finally, a word on the tests employed for the detection of arsenic. Considerable controversy has arisen as to the respective merits and demerits of the various tests for arsenic. In our experience the Gutzeit test is the most satisfactory for qualitative purposes, and to some extent for quantitative purposes also, so long as special care be taken to absorb any sulphuretted hydrogen that may be evolved. It has the advantage over the Reinsch test of giving indication of the presence of arsenic even if it be in the form of arseniate or arsenic acid. Reinsch's test is not at all satisfactory when the arsenic is present in the form of arseniate or arsenic acid unless steps be taken to reduce the arsenic to the arsenious state. Sulphur compounds again seriously interfere with the Reinsch test, sulphur depositing upon the slip of copper and complicating the result. All fallacy, however, may be got over by first oxidising the liquid, such as beer, which frequently contains sulphates with a little excess of bromine, driving off the bromine and then reducing the arsenic by the addition of some cuprous chloride solution. If arsenic is present the liquid will yield an immediate deposit on the copper on boiling after acidulating the liquid with hydrochloric acid. The Gutzeit test is best conducted in a six-ounce flask fitted with a small glass tower containing filter paper saturated with acetate of lead. Over the top of the glass tower is placed a piece of filter paper moistened with strong mercuric chloride solution and afterwards dried. The production of a yellow stain in intensity varying directly with the amount of arsenic present is a certain indication of arsenic when the precautions indicated are taken. Complex liquids like beer may be first evaporated with sulphuric acid and most of the charred material destroyed as in the Kjeldahl process for the estimation of nitrogen. The acid liquid may be filtered if necessary or it can be carried to a clear state by continued heating. It is then transferred to the flask in which the hydrogen is generated by the action of acid upon pure zinc. Arseniates and arsenic acid respond to this test most distinctly in a few minutes. By attaching a small glass tube to the tower the result may be confirmed by obtaining the black arsenical deposit as in the case of Marsh's test.

The Lancet Laboratory.

THE WAR IN SOUTH AFRICA.

THE news from South Africa is of a very mixed and not altogether satisfactory character. Nor is it likely that anything short of the capture of De Wet and the complete and final dispersal of his forces will make it otherwise. The occupation of all the stations along our lines of communication by strong bodies of infantry to guard against attack, while bodies of mounted troops are actively pursuing and dealing with the Boer forces may result in this. The most unsatisfactory part of the news at the moment is that the Boers are raiding Cape Colony. We must, presumably, make up our minds that the guerilla war will pursue its course for a time, giving rise to surprises, small disasters, and "regrettable" events. The wide extent of territory to be held and safeguarded against attack, as well as the distances over which the operations are spread, will probably require the presence of larger mounted forces than are at present in the field. The Colonial Governments, we are proud to say, are showing themselves alive and equal to the situation; that of New Zealand, for example, is taking up steamers for the conveyance of a fresh contingent of troops to South Africa.

We regret to notice that enteric fever is still very prevalent, and that it, together with dysentery and other camp diseases, gives rise to numerous deaths. Nor is this to be wondered at considering that a recrudescence of enteric fever was only to be expected, as we have already foreshadowed, on the approach of warmer weather.

Further reports respecting the Imperial Yeomanry Hospital at Deelfontein from Lieutenant-Colonel A. T. Sloggett, R.A.M.C., show that on Dec. 10th there remained in hospital 17 officers and 443 non-commissioned officers and men, of whom nine officers and 322 men belonged to the Imperial Yeomanry. Colonel Sloggett adds that Surgeon-Dresser Ransford, of the hospital staff, and Nursing Sister Timbrell, of the Pretoria staff, were both convalescent, and that Surgeon-Dresser Blathwayt, of the Deelfontein staff, suffering from enteric fever, was progressing favourably. There had been a decided increase of enteric fever of late. Surgeon-Major C. R. Kilkelly, of the Grenadier Guards, commandant of the hospital at Pretoria, announced on Dec. 5th that there remained in the hospital 55 officers and 388 non-commissioned officers and men. A convoy of wounded from Bronkerspruit, consisting of 11 officers and 20 men, had just arrived.

DENTAL SURGERY WITH THE FIELD FORCE IN SOUTH AFRICA.

BY F. NEWLAND-PEDLEY, F.R.C.S. ENG., L.D.S.,
RECENTLY DENTAL SURGEON TO THE IMPERIAL YEOMANRY HOSPITAL AT DEELFONTEIN.

The following record of my experiences, which was written whilst I was on service in South Africa, is intended to indicate the defects of our military system as regards the care of our soldiers' teeth. For reasons that will be easily understood I deferred the publication till a more suitable time than that of my actual service.

Early in February, 1900, I left England with the staff of the Imperial Yeomanry Hospital as a consulting dental surgeon to treat the special cases of injuries and diseases of the jaw, and for nearly six months I worked under varied conditions—on board ship, in a tent, afterwards in a shanty, and subsequently in a hut. Here I settled down into a daily routine which little resembled what I expected to do, but which seemed to meet the requirements of a large camp as far as the work of one dental surgeon can be said to supply the needs of a general hospital.

Occupation for me was never lacking from the first day of the outward voyage, for there was the usual epidemic of influenza followed by numerous cases of neuralgia and

toothache. I had to attend patients nearly every day, although I had only a few instruments available. I managed to do some temporary fillings and some extractions, including a badly impacted wisdom tooth. The patient was an officer who was suffering from trismus, and as he was just recovering from an attack of bronchitis ether was unsuitable as an anæsthetic; so, much against our inclination, we had to give him chloroform in his bed, and in dislodging the impacted tooth I had to rely exclusively on sense of touch.

After two days at Cape Town we were ordered to Deelfontein, which is nearly 500 miles north of the Cape. I had a world of trouble in taking my two or three tons of equipment with me, and when I arrived at the camp we were all under canvas and it was premature to unpack instruments of value. We had quite enough to do to keep ourselves dry and to prepare accommodation for expected patients. Even whilst we were living in tents there was something for me to do in seeing urgent cases of dental trouble, especially amongst the sick. Under such circumstances one cannot do much beyond extractions, and I had to seat the patient in a deck chair and support his head against the tent pole by way of securing a fixed point. At this period the newspapers announced that there was a dental surgeon in our camp, and applications soon poured in from all sides for dental treatment, but I could do little for the applicants as I was unwilling to unpack good instruments before I had a water-tight roof. By way of a temporary resting-place I was promoted to a shanty 10 feet square with a tarpaulin roof. This dear little place, which subsequently became a mortuary, I used for a time as a dental surgery and also as the office of a camp journal which I started under the title of the *Devil's Fountain*.

On March 25th a complicated fractured jaw case arrived and as it was necessary for me to unpack my workroom appliances in order to construct a special splint I was moved into a hospital shed which I converted into a work-room and bedroom combined, and I had the use of the second or reserve operating-theatre of the hospital for my consultations and operative work. The workroom was 27 feet long and 16 feet wide, and it was constructed of sections fastened together with bolts and nuts, so that it could be readily taken down and put up elsewhere if desired. Each section was 8 feet long, 5 feet 6 inches wide, and 4 inches thick, and it consisted of an outer layer of galvanised iron nailed on to a rough wooden frame and lined with deal boards. It was lit by four windows, each 3 feet 6 inches by 2 feet 6 inches. These huts, or sheds, were much cooler than tents in summer and were a much better protection against rain. For winter they were rather too well ventilated, as there was an open space of four inches all round the eaves, and there were about 50 large square holes in the woodwork where the sections were bolted together. A fine breeze blew upwards between the floor-boards and there was a wide chink round the floor which admitted a further supply of fresh air. The cost of a similar shed better made and finished would be about £50 in England, but these sheds were made in Cape Town and were inferior in every respect to the English huts excepting in the matter of mobility. The draught under the boards could be reduced by piling earth round three sides of the foundation, and the industrious person who had the foresight to bring his own carpenter's tools could quickly exclude the frosty night air. With these slight improvements the shed made a very suitable workroom and here I set up a casting bench, a plaster bench, and a jeweller's bench, with vulcaniser, lathe, and all necessary appliances. A smaller room would be sufficient for a workroom if additional space were afforded for storage and for a bedroom, but in a country where commandeering is recognised as a fine art and tools are in great request the dental surgeon who elects to combine his sitting-room, bedroom, and store-room with his workroom is wise. I covered the ugly walls with numerous prints and engravings, many of which I framed (see Figure). This kind of workroom may be considered perfectly satisfactory for two or three mechanical assistants, in addition to which there is space for one bed 2 feet 6 inches wide.

Dental workroom at the Imperial Yeomanry Hospital, Deelfontein.

My operating and consulting-room adjoined the operating theatre and x ray room, and could be used at any moment as a second surgical theatre if it were necessary to perform two

operations at the same time. The room was 19 feet by 16 feet, and was lit by seven windows. An attempt at top-lighting had been made, but it could not be said that the light was really good for dental manipulations. In this room I placed an operating chair, a dental engine, and all the instruments, appliances, and materials that I required for practice. There were, in reserve, a second engine and two more operating chairs for the use of possible assistants. I worked strictly by appointment for all cases requiring fillings, and the ophthalmic surgeon was kind enough to give gas every day at 11.30 A.M. punctually. Some surprise may be felt that one should give gas to a soldier for the extraction of a tooth—and it would not be necessary if the patients were not sick, but hundreds of them were recovering from typhoid fever and dysentery, which left them in a very weak state. A man with nine bullet-wounds, who was known amongst his friends as the man who stopped a whole volley, was a very brave fellow, but he was glad to take gas for a severe extraction. A patient was sent to me with a history of thoracic aneurysm and I decided to use gas in the extraction of an aching tooth, believing that the pain of the operation would be more dangerous than the anæsthetic. An appointment for the next day was made with Mr. L. V. Cargill and the surgeon in charge of the case, but the aneurysm ruptured into the œsophagus during the night and the patient died.

The work required of me at Deelfontein was little more than the work of a dental practitioner and I only had a very few severe gunshot cases which I treated in conjunction with Mr. Alfred Fripp. Gold fillings are rarely necessary in a military camp, but the percentage of exposed pulps is very high, as nearly every patient would rank as a neglected case. Disease, neglect, tough beef, and hard biscuit play havoc with the teeth—one young man had only three useful teeth left. How such patients recover from typhoid fever and dysentery is a mystery. They are of no further use as fighting men under the present *régime*, for they cannot eat service food Nothing is done to preserve the soldier's teeth whilst he has any and when they are gone he must go home as a man unfit for service. It would be better and quicker to put a soldier's teeth in order than to train a fresh man as a substitute for the invalid. The officers suffer with their teeth after a few months' campaigning, and I hear on the best authority that there were at one time at Modder river 80 officers requiring dental attention and they sent to Cape Town for a dental surgeon. Unfortunately, they were again on the march when he arrived.

The selection of cases for hospital treatment and the limitation of work was most perplexing, and without the exercise of a good deal of discretion the dental surgeon in such a situation will find himself attending the patients who have the least claim on his time. I thought that some patients who were able to go to Kimberley or Cape Town might be recommended to consult practitioners in those towns, for there were in the beds of the Imperial Yeomanry Hospital a great many more patients than I could attend.

TO SAVE THE TEETH OF AN ARMY.

One is compelled to face the question, Can nothing be done to save the teeth of an army? and regarding my appointment as being somewhat of an experimental nature I think I should be fulfilling the wishes of those interested in the welfare of our brave "Tommies" if I were to attempt to devise a scheme under which the army in time of war could be provided with dental practitioners. I purposely allude to war times, for if it can be shown how to deal satisfactorily with the teeth of an army threading its way over 1000 miles of South African territory it will be comparatively easy to attend to the soldiers' teeth at home. At first sight it might seem desirable to attach a dental surgeon to each regiment, brigade, or division. Experience in South Africa, however, has left no doubt in my own mind that it would be better to make such appointments to the general hospitals, and perhaps to the stationary hospitals also, where the transport rations and sleeping accommodation for two or three such dental officers could easily be added to that already required for the staff of 21 medical officers. Each of the numerous general or base hospitals in South Africa should have been provided before it left England with a dental unit consisting of one dental surgeon and two senior dental students as assistants. In Deelfontein it would have been impossible for me adequately to tackle the dental work of our 1000-bedded hospital without at least two assistants. What must the condition have been in the general hospitals at Cape Town, Kimberley, Naauwpoort, and Bloemfontein? My chief experience was drawn from our camp of 1000 souls, but in the latter place alone there were 5000 sick in hospital, to say nothing of the 30,000 troops left encamped there after Lord Roberts moved north with the bulk of his army. At each general hospital there should be an operating-room with three chairs and a workroom for the construction of special appliances and dentures. Each stationary hospital of 200 beds should similarly have a dental surgeon upon its staff, but workroom appliances are cumbrous and heavy as compared with surgical instruments, and all patients requiring dentures should be sent to the general hospitals. The dental units should be supervised by the chief dental officer at the base in the same way that the principal medical officer supervises all medical units.

To meet emergencies and the requirements at the actual front—as, for example, after a great battle or during a protracted halt of the army—the principal dental officer should have a small reserve of dental officers who could be drafted to any point on the receipt of the necessary intelligence from headquarters. The equipment of the dental officers who were sent to the front would, of course, be as light as possible. The dental engine packs into a small space and all the necessary instruments and materials would go into a case one cubic foot in measurement. Dental officers at the front could obtain additional supplies if necessary from the nearest general hospital. No special operating chair should be taken to the front; all that is necessary is a portable headrest that can be fixed on to any chair. In large hospitals portable operating chairs weighing 80 pounds each and costing seven guineas would be useful, and a strong operating chair for anæsthetic operations would be desirable in addition.

The manner in which the dental officers are to be found and some indication of the expense may now be given. I believe that dental surgeons to act as heads of units could be obtained in any war on similar terms to those which were given to the civilian medical officers in the present war. Every unit would thus contain one good dental surgeon who should preferably be a teacher from one of the dental schools. Two senior dental students who would act as dental assistants to him would easily be obtained at very small expense, and it would be better if the dental surgeon were allowed to select his own assistants. When I was leaving England I obtained a list of the names of my pupils who would follow me to act as assistants or dressers, and at least a dozen gave in their names. The conditions arranged were that each of them would serve for at least six months, receiving a first-class passage and maintenance in any hospital to which they might be attached, together with remuneration at the rate of £75 per annum as pocket-money. Each student was to bring his own dental engine and student's set of instruments, the value of which would be about £30. I communicated with the Royal College of Surgeons of England and they undertook to recognise six months' service in South Africa as the equivalent of a like period spent in a hospital at home. At the Imperial Yeomanry Hospital we had a suitably equipped workroom and operating-room, so that if it had been desired to test the work of a dental unit in a general hospital it would only have been necessary for the War Office to sanction the sending out of two of the pupils whom I selected. I applied for these assistants and I had more than enough work for them. The committee in London who manage the affairs of this hospital acquiesced in my request for them to be sent, of course at the expense of this hospital and not at that of the War Office; but the latter absolutely refused to endorse the appointment of more than one dental attendant to this British army of about 200,000 officers and men. My chief wonder is that Mr. Fripp succeeded in getting them to allow even that one to be included in the staff of the Imperial Yeomanry Hospital.

ROYAL BRITISH NURSES' ASSOCIATION.—The offices of this association have been removed to new premises at 10, Orchard-street, Oxford-street, W., where all communications for the future should be addressed. On Jan. 17th Mrs. Humphrey Ward will open a discussion in the new rooms of the association on the Education of Crippled Children in which the matrons of various children's hospitals will take part. Tickets may be obtained from the secretary.

BOROUGH COUNCILS AND THE HOUSING OF THE DISSOLUTE POOR.

WITH the new year the new borough councils will have got sufficiently into harness to commence their work of local administration and reform. They are intended to replace the old, and in too many instances, the effete, vestries; and for this purpose they have been armed with more extensive powers and endowed with higher dignity. The Londoner waits anxiously for some good result.

Of all the questions which demand immediate attention and action the housing problem stands first. Past experience is not encouraging, for the grievance is becoming more and more acute and it is the deserving as well as the undeserving who now suffer. It is not only the poor but the comparatively well-to-do artisan who cannot find a suitable home. Though from a sanitary point of view it is the thriftless, the filthy, the vicious, and the intemperate, who create the greatest danger of epidemic disease, from the political and social point of view the fact that more worthy members of the community are in great difficulties is likely to have influence in determining the local authorities to take action. Thus it must be hoped that the agitation arising from the suffering of a better class may help to bring relief not only to themselves but to those who are even less fortunate. Nevertheless it will be necessary to bring much pressure to bear, for past experience has shown how evils accumulate more rapidly than improvements are effected. When we remember that 16 years have already elapsed since one of the most weighty of Parliamentary commissions ever held reported on the question of the housing of the poor, and that comparatively little has yet been done, apprehensions as to the slowness of future progress may well be entertained. It is against further delay that we must act with all possible energy. Six years elapsed before the work of the Royal Commission of 1884 was embodied in the Housing of the Working Classes Act of 1890. Then it was thought that by the creation of a county council for the metropolis a local authority would be brought into existence that would be better able to apply the provisions of this Act. But that, again, required much time and the London County Council did not for several years fully realise the powers it possessed. It is maintained that the Council at first did not appreciate the importance of Part III. of the Act, which embodies Lord Shaftesbury's Act of 1851—a good law badly or feebly applied. The Council then studied in preference Parts I. and II. of the Act, under which the land acquired by the local authority must be sold, while under Part III. the local authority may retain the property. As it had been reported to the Council that 214,840 persons were living in one room, and that 128,000 families of from four to twelve persons had not more than one room, the necessity of taking action was but too evident. It was likewise stated a few years ago that the artisans' dwellings companies had ceased building, so that matters were drifting from bad to worse. This of course was a state of things shocking to contemplate.

As a remedial measure the Housing Committee of the London County Council gave details concerning 30 plots of vacant land within the boundaries of the metropolis which might be bought. They also now began to insist on the value of Part III. of the Act. About a million sterling has been spent to purchase and pull down insanitary property, and model dwellings have been raised instead of old rookeries, but the tenements thus brought into existence contain about 4000 persons less than those which were destroyed. This is a great sanitary improvement but it does not relieve the pressure on house space. To further complicate matters there were differences of opinion between some of the local vestries and the Council. At least one vestry was anxious that the Council should deal with their insanitary areas under Part III. of the Act, that it should acquire the property and put it all in order. The Council, on the other hand, was not particularly anxious to assume such responsibilities in regard to houses that had no structural sanitary defects and replied that the grievances might be dealt with by vestries by more energetic inspection under their by-laws or under the Public Health (London) Act of 1891. Whatever may be the merits of this contention it has been definitely set at rest by conferring on the borough councils themselves the right of applying Part III. of the Act to their own district. They can, therefore, now do what their predecessors, the vestries, asked the London County Council to take in hand, so that if it be true that the impediment in the past has been the slowness of action of the Council this need not affect the future.

The borough councils, however, will now have to examine with the greater care that responsibility engenders whether the vestries were always right when they desired to see Part III. of the Act applied to insanitary areas. The problem is complex and a remedy suited to one insanitary area does not apply to another. The question in some localities is whether a high death-rate alone suffices to qualify houses as insanitary. Some of the highest death-rates occur in houses that cannot, as dwellings, be qualified as insanitary. The streets are broad and there are wide open spaces and big yards behind the houses. The rooms are lofty, the houses are modern, and the drainage if anything is above the average, the drains being carefully trapped and ventilated. Perhaps the subsoil may be at fault or the street sewers may be of insufficient gradient to be self-cleansing, though these are defects that would not be altered by the municipalisation of the houses. Yet death-rates that exceed 40 per 1000 per annum occur in such dwellings. Topographical conditions and bad street sewers may account for some of the ill-health prevailing, but it is self-evident that the principal causes are the habits of the people themselves and overcrowding. This is not a theoretical contention, there is practical proof of its truth. In the same streets there are common lodging-houses and there the death-rate and the sick-rate are somewhat lower. On the other hand, it may justly be argued that this would inevitably be the case as there are fewer children in common lodging-houses than in tenement houses; but against this argument it can be maintained that though there are fewer children, on the other hand the inhabitants of the common lodging-houses are poorer and endure greater privations than those of the tenement houses. One thing, however, is certain—namely, that the common lodging-houses are much cleaner than the private tenement houses, even when the latter, being registered, are open to constant inspection. The contention is that in some districts the inspection of registered tenement houses has not been carried out properly; and it is said that the vestries, instead of asking the Council to buy up this property, should have appointed more inspectors and have kept it under better control.

There can be no doubt that many more inspectors are needed; but the most elaborate system of inspection will not alter economic conditions. The application of Part III. of the Act may contribute to this result; the action of inspectors might, if anything, aggravate the economic difficulty. In more than one specially insanitary area there stand side by side common lodging-houses and registered tenement houses. The old Common Lodging-houses Act applies to the former, the only alteration being that the inspectors are now under the London County Council instead of under the Metropolitan Police. The staff of inspectors is numerous, the most rigorous control is exercised, and the inspection is so frequent that cleanliness is maintained and overcrowding is prevented. In some cases a common lodging-house and a registered tenement house are owned and managed by the same proprietor; they are sometimes in the same street and stand side by side, yet there is no fault to be found with the one, while the other is overcrowded, filthy, and in a deplorable condition. It seems quite natural to conclude that the one inspected by the London County Council inspectors is well inspected and the other badly inspected. The borough councils are, therefore, urged not to follow the parsimonious policy of the vestries but to appoint a much larger number of inspectors. Unfortunately, it does not follow that what is successful with regard to common lodging-houses would be equally effective with regard to the registered tenement houses. The position socially and economically is different. The common lodging-houses are inhabited mainly by single men, single women, and a smaller number of adult couples; the tenement houses, on the contrary, are to a large extent occupied by families. It is the children who very generally cause the overcrowding, who add to the foulness of the atmosphere, and who certainly do not help to keep the rooms clean and tidy. Many of these tenement houses are not structurally

defective. It is the dirt and the overcrowding, the vicious lives, the insufficient food and clothing, &c., which are the principal causes of the high death-rate. To improve these conditions would mean that more money must be spent; and where is the money to come from?

This is the point where the advocates of the application of Part III. of the Act step in. They say that the high death-rate is a sufficient reason, without there being structural sanitary defects, to justify the sanitary authority, whether county council or borough council, in acquiring the property. It is not proposed that in every instance the houses thus purchased should be pulled down and rebuilt. The first of all necessities is to reduce the rents, and a municipal authority could afford to let two rooms for the price now charged for one room. But if this were done, where to-day we have two tenants each renting a room one of these tenants would have to go away so that the remaining tenant might have two rooms instead of one. This might be met either by building new houses on vacant sites or by making better use of some of the space now built upon and erecting in the place of existing small cottages large tenement model dwellings. In all this the first thing to be done is to reduce the rents and to increase the accommodation. Then, and after that is accomplished, it will be necessary to have a very constant and elaborate system of inspection. However cheap the rents may be, there is no inconsiderable section of the population which will still continue to overcrowd and to live in filth, if they can save any rent money to spend in some form of dissipation or enjoyment. But this must be prevented by the strong arm of the law. If the local authorities incur the responsibility and expense of carrying out large schemes for the rehousing of the poor it is for the purpose of preventing overcrowding and insuring cleanliness. It is at this stage that inspection will produce the best results. But at present what is an inspector to do?

We have visited at one time or another not a few of these insanitary areas and we cannot better illustrate the difficulties than by describing some cases. In the small back first floor room of a house originally built to accommodate one single family we found a woman and her husband. The man was a coachman, but being addicted to drink he had been discharged and was out of work. The woman was just recovering from a dangerous attack of pleurisy, and had also suffered from erysipelas. She was able to make dresses and she sewed very well, but in consequence of her illness and the bad repute of the street in which she lived, she could not get any work. The couple were simply starving. They had seen better days and they confessed to have fallen in the main through their own fault, but this did not lessen the difficulty. Indeed, the fact that the people are themselves often very much to blame only adds to the complications of the problem. They paid 4*s*. 6*d*. per week for their very small room; it was supposed to be let furnished with all necessary utensils. These necessary utensils consisted of a saucepan with three holes in it and a kettle without a spout. The bed, with several of the laths broken, stood by the window. One of the panes of glass had been broken, so that for some time the bedclothes were damp with the rain that came through. Now the window had been repaired, not by putting in a new pane of glass, but by sticking fragments of glass over the broken part of the old pane. The sheets of the bed, provided by the landlord, were well-nigh black, and the tenant explained that if she washed them herself she had to wait till they were dry and to sleep without sheets in the meanwhile. Now if by constant inspection the landlord was made to furnish this room properly, would he not increase the rent? Again, if the bedding and the utensils were in a better condition might not the tenants be tempted to pawn or sell some of them? In another small back room we found a woman suffering from pulmonary tuberculosis. Her husband tried to make a little money by selling in the streets some lamp-glass cleaners of his own manufacture, but being lame, he found it very painful to stand about. Here again the rent was 4*s*. 6*d*. a week and it was evident that these people were rarely able to obtain sufficient food. In a large front room there was a woman with so numerous a family that complaints had been made against her of overcrowding. She then sent two of her boys to a neighbouring common lodging-house, but they met such rough company there that she finally took a second room in the house and had to pay 9*s*. a week rent for the two rooms. How was this to be done now that her husband, a labourer, was out of work?

To attack these people for overcrowding when they are already starving themselves so as to pay extortionate rents does not seem a very humane or a very practical proceeding. But if these houses, instead of being in the hands of persons who unscrupulously speculate on the misery of the poor, were owned by the borough council they might be kept clean, be simply but properly furnished, and be let out at much lower rents. They would however, require very keen and constant supervision and the question is whether, in the face of such control, the same dissolute class of people who now inhabit them would remain. If they did not then it would simply mean that the difficulty would be transferred to some other locality. In Fulham we came across a case in point. A woman, her husband, and some of her children slept in one room. Then she had on the staircase landing a sort of lumber-room, in which she managed to squeeze a bed and one chair. Here three of her children slept. A sanitary inspector warned her against overcrowding, so she sent two of her children to sleep with a friend who lived in the same street, and where there was more room. The sanitary inspector imagined that he had put an end to the overcrowding; but no sooner had he expressed his satisfaction than she secured two lodgers, journeyman bakers, who came in late at night and left early in the morning, and were able to sleep in the little room without attracting any notice. This is the sort of thing that will constantly occur. If a family are all living in one room to-day, and in the course of time, through the benevolent action of a borough council, they are given two rooms for the same rent, the chances are that they will sublet the second room and continue to overcrowd just as before. Then it is that strict inspection will be necessary to find all this out and prevent its occurrence. But while the extreme poor are called upon to pay, as in the typical cases described, 4*s*. 6*d*. for a small back room, 6*s*. for a larger front room, and 9*s*. per week for two rooms, one small and one large, it is scarcely fair to complain of overcrowding, for we must take into consideration that many of these people consider themselves fortunate if they earn 12*s*. in a week. Many sell flowers, toys, and other objects in the streets, or live by petty thieving; a more skilful or a professional thief is often better lodged. The women sometimes belong to the lowest class of prostitutes, and whatever may be the expedients by which they live, it is quite certain that they cannot afford to pay high rents. Yet it is precisely this class that pays, in proportion to the accommodation received, higher rents than any other class of the community. The more dissolute the class the higher the rent charged by those who cater for them.

Of late years the problem has presented itself in a comparatively speaking novel aspect. It was supposed that the lowest class lived in low-class dwellings that were so insanitary and dilapidated that the first thing to be done was to pull the houses down. In many instances this is no longer the case. They, on the contrary, live in modern houses of the middle-class type that possess no structural defects and are well drained. But the tenants overcrowd these houses, and such is their poverty, and their dissolute, drunken, dirty habits, that in spite of good drainage and good houses the death-rates in certain areas of this description are generally above 40 per 1000 per annum and have sometimes exceeded 50 per 1000. It is proposed to make this high death-rate the pretext for municipalising such property; but if the compensation given to the owners of such property is sufficiently high, will not this constitute a premium to those who allow their property to be degraded by the advent of tenants of this class? Are borough councils competent to become the landlords of the most dissolute and unmanageable section of the community? It is a heavy responsibility, though it is difficult to see by whom else the work can be undertaken. The London County Council shrank from the hazards of such an undertaking: will the borough councils display greater courage and enterprise? If the rents are to be reduced—and surely they must be reduced—the profits will be too small to tempt private enterprise. At first the strict regulations and the constant inspection that will be necessary to keep such property in order will have a tendency to drive away the more dissolute among the tenants. They will prefer to pay higher rents to the private speculator who will allow them to overcrowd and to wallow in the dirt which they often much prefer to cleanliness. But when the local authorities are able to provide, at low

rents, proper accommodation they will then be justified in prosecuting those who prefer to live in insanitary conditions.

High rents are as effective a cause of high death-rates as defective drainage, since the high mortality occurs where the drainage and structure of the houses are not at fault, where the streets are broad and the open spaces behind the houses are ample. Of the submerged, those who have sunk deepest in the mire stand first in need of municipal intervention on their behalf. It is in catering for them that private enterprise has most conspicuously failed and therefore municipal enterprise would be most justifiable. Private enterprise only succeeds because it tolerates overcrowding. Private enterprise which only prospers by breaking the law may well be suppressed. If it can compete with municipal enterprise that observes the law, well and good, if not, it does not deserve to exist. Private enterprise subdivides into tenements a house worth £40 a year and charges £90 a year to the sub-tenants. Municipal enterprise need not charge more than £40 or £45 a year for the same tenements, and it can do this without increasing the rates. Why, then, should London wait? All that is necessary is to so arrange matters as to prevent the payment of such exaggerated compensation or purchase money as would handicap municipal enterprise by entailing too large an expenditure of capital. For instance, if a house worth £40 a year brings in £90 a year because it is subdivided into small tenements and overcrowded by the lowest class of tenants the compensation for expropriation should be estimated on the £40 annual valuation and not on the £90. On this basis the rehousing even of the poorest and the most dissolute class could be made to pay, and from the sanitary point of view it is for this class that action is most urgently needed. From the moral point of view, though some of these people dearly love the dirt and disorder in which they live, others, on the contrary, would eagerly profit by any opportunity of raising themselves. In this cause, therefore, the social reformer and the sanitary reformer can press forward hand in hand.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN 33 of the largest English towns 6157 births and 3590 deaths were registered during the week ending Dec. 22nd. The annual rate of mortality in these towns, which had been 18·0, 17·7, and 16·8 per 1000 in the three preceding weeks, further decreased to 16·1 during the week under notice. The death-rate in London was 15·7 per 1000, while it averaged 16·4 in the 32 provincial towns. The lowest death-rates in these towns were 10·1 in Derby, 11·6 in West Ham, 12·3 in Norwich, and 12·5 in Burnley; the highest rates were 19·6 in Liverpool, 20·6 in Preston, 22·2 in Salford, and 22·3 in Birkenhead. The 3590 deaths in these towns included 351 which were referred to the principal zymotic diseases, against 363 and 328 in the two preceding weeks; of these, 103 resulted from diphtheria, 76 from whooping-cough, 52 from "fever" (principally enteric), 48 from measles, 39 from diarrhœa, and 33 from scarlet fever. No death from any of these diseases occurred during the week under notice in Norwich; in the other towns they caused the lowest death-rates in Plymouth, Derby, Huddersfield, and Gateshead, and the highest rates in Leicester, Burnley, Blackburn, and Sheffield. The greatest mortality from measles occurred in Swansea; from scarlet fever in Burnley; from whooping-cough in Croydon, Nottingham, and Sunderland; and from diarrhœa in Wolverhampton and Birkenhead. The mortality from scarlet fever showed no marked excess in any of the large towns. The 103 deaths from diphtheria included 36 in London, 20 in Sheffield, 11 in Leicester, and five in Blackburn. No fatal case of small-pox was registered in any of the 33 towns, and only one small-pox patient remained under treatment in the Metropolitan Asylums hospitals on Saturday, Dec. 22nd. The number of scarlet fever patients in these hospitals and in the London Fever Hospital at the end of the week was 2406, against numbers decreasing from 2728 to 2617 on the five preceding Saturdays; 218 new cases were admitted during the week, against 279, 259, and 255 in the three preceding weeks. The deaths referred to diseases of the respiratory organs in London, which had been 435, 400, and 349 in the three preceding weeks, further declined to 306 during the week under notice and were 204 below the corrected average. The causes of 45, or 1·3 per cent., of the deaths in the 33 towns were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in West Ham, Nottingham, Bradford, Leeds, Newcastle, and 11 other smaller towns. The largest proportions of uncertified deaths were registered in Birmingham, Liverpool, Sheffield, and Gateshead.

During the week ending Saturday last, Dec. 29th, 1900, 4178 births and 3773 deaths were registered in 33 of the largest English towns. The annual rate of mortality in these towns, which had been 17·7, 16 8, and 16·1 per 1000 in the three preceding weeks, rose again last week to 16·9. In London the death-rate was 16·7 per 1000, while it averaged 17·1 in the 32 large provincial towns. The lowest death-rates in these towns were 9·5 in Huddersfield, 10·2 in Cardiff, 10·7 in Leicester, and 10·9 in Halifax; the highest rates were 20·9 in Newcastle, 21·4 in Birkenhead, 22·4 in Liverpool and in Preston, and 23·2 in Hull. The 3773 deaths in these towns included 334 which were referred to the principal zymotic diseases, against 328 and 351 in the two preceding weeks; of these 88 resulted from whooping-cough, 78 from diphtheria, 59 from measles, 46 from "fever" (principally enteric), 34 from diarrhœa, and 29 from scarlet fever. No death from any of these diseases occurred last week in Wolverhampton, Norwich, and Huddersfield; in the other towns they caused the lowest death-rates in Croydon, Brighton, and Sunderland, and the highest rates in Nottingham, Salford, Blackburn, and Preston. The greatest mortality from measles occurred in Swansea; from whooping-cough in Derby, Nottingham, Salford, Preston, and Sheffield; and from diarrhœa in Gateshead. The mortality from scarlet fever and from "fever" showed no marked excess in any of the large towns. The 78 deaths from diphtheria included 26 in London, nine in Sheffield, five in Leicester, five in Liverpool, and five in Blackburn. No fatal case of small-pox was registered last week either in London or in any of the 32 large provincial towns, and only one small-pox patient remained under treatment in the Metropolitan Asylums Hospitals on Saturday last, Dec. 29th. The number of scarlet fever patients in these hospitals and in the London Fever Hospital at the end of the week was 2535, against numbers decreasing from 2727 to 2477 on the four preceding Saturdays; 167 new cases were admitted during the week, against 259, 255, and 218 in the three preceding weeks. The deaths referred to diseases of the respiratory organs in London, which had declined from 435 to 306 in the four preceding weeks, rose again to 325 last week, but were 235 below the corrected average. The causes of 77, or 2·1 per cent., of the deaths in the 33 towns were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Bristol, Nottingham, Salford, Leeds, and 14 other smaller towns; the largest proportions of uncertified deaths were registered in Liverpool, Preston, Sheffield, Gateshead, and Newcastle.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in the eight Scotch towns, which had been 21·7, 20·7, and 19·3 per 1000 in the three preceding weeks, further declined to 18·2 during the week ending Dec. 22nd, but showed an excess of 2·1 per 1000 over the mean rate during the same period in the 33 large English towns. The rates in the eight Scotch towns ranged from 11 3 in Leith and 16·4 in Dundee to 21 5 in Greenock and 28·7 in Perth. The 563 deaths in these towns included 26 which were referred to whooping-cough, 15 to diarrhœa, 12 to measles, eight to diphtheria, seven to scarlet fever, five to "fever," and one to small-pox. In all 74 deaths resulted from these principal zymotic diseases, against 87 and 79 in the two preceding weeks. These 74 deaths were equal to an annual rate of 2·4 per 1000, which was 0·8 above the mean death-rate from the same diseases in the 33 large English towns. The fatal cases of whooping-cough, which had been 31 and 33 in the two preceding weeks, declined again during the week under notice to 26, of which 22 occurred in Glasgow, two in Paisley, and two in Greenock. The deaths from diarrhœa, which had decreased from 20 to 10 in the four preceding weeks, rose again to 15 during the week ending Dec. 22nd and included 10 in Glasgow, three in Dundee, and two in Paisley. The fatal cases of measles, which had increased from eight to 16 in the four preceding weeks, declined again during the

week under notice to 12, of which seven were registered in Edinburgh, two in Glasgow, and two in Aberdeen. The eight deaths from diphtheria showed an excess of five over the number in the preceding week and included five in Glasgow and two in Leith. The fatal cases of scarlet fever, which had been nine and eight in the two preceding weeks, further declined during the week under notice to seven, of which four occurred in Glasgow. The five deaths referred to different forms of "fever" showed a slight decline from the number in the preceding week and included four in Glasgow, where the fatal case of small-pox was also registered. The deaths referred to diseases of the respiratory organs in these towns, which had been 151 and 136 in the two preceding weeks, further declined to 111 during the week ending Dec. 22nd and were 72 below the number in the corresponding period of the preceding year. The causes of 32, or nearly 5 per cent., of the deaths in these eight towns were not certified.

In eight of the principal Scotch towns the annual rate of mortality, which had declined from 21·7 to 18·2 per 1000 in the four preceding weeks, rose again to 20·4 during the week ending Dec. 29th, and showed an excess of 3·5 per 1000 over the mean rate during the same period in the 33 large English towns. The rates in the eight Scotch towns ranged from 8·4 in Perth and 17·5 in Edinburgh to 22·6 in Aberdeen and in Paisley, and 25·8 in Greenock. The 638 deaths in these towns included 33 which were referred to whooping-cough, 18 to diarrhœa, 12 to measles, nine to diphtheria, seven to "fever," five to scarlet fever, and three to small-pox. In all, 87 deaths resulted from these principal zymotic diseases, against 79 and 74 in the two preceding weeks. These 87 deaths were equal to an annual rate of 2·8 per 1000, which was 1·3 above the mean rate last week from the same diseases in the 33 large English towns. The fatal cases of whooping-cough, which had been 33 and 26 in the two preceding weeks, rose again last week to 33, of which 28 occurred in Glasgow, two in Dundee, and two in Greenock. The deaths from diarrhœa, which had been 10 and 15 in the two preceding weeks, further rose to 18 last week, and included six in Glasgow, five in Dundee and four in Aberdeen. The fatal cases of measles, which had been 16 and 12 in the two preceding weeks, were again 12 last week, of which nine were registered in Aberdeen and two in Edinburgh. The deaths from diphtheria, which had been three and eight in the two preceding weeks, further increased to nine last week, and included three in Glasgow, two in Edinburgh, and two in Aberdeen. The fatal cases of "fever," which had been six and five in the two preceding weeks, rose again last week to seven, of which six occurred in Glasgow. The deaths from scarlet fever, which had declined from 9 to 7 in the three preceding weeks, further declined to 5 last week, and included two in Glasgow and two in Paisley. The three fatal cases of small pox were all recorded in Glasgow. The deaths referred to diseases of the respiratory organs in these towns, which had declined from 160 to 111 in the four preceding weeks, rose again last week to 121, but were 132 below the number in the corresponding period of last year. The causes of 38, or nearly 6 per cent., of the deaths in these eight towns last week were not certified.

HEALTH OF DUBLIN.

The death-rate in Dublin, which had been 27·4 and 25·8 per 1000 in the two preceding weeks, further declined to 25·7 during the week ending Dec. 22nd. During the four weeks ending on that date the death-rate in the city has averaged 25·9 per 1000, the rate during the same period having been 16·9 in London and 19·6 in Edinburgh. The 172 deaths belonging to Dublin registered during the week under notice included 16 which were referred to the principal zymotic diseases, against 11 and 12 in the two preceding weeks; of these, six resulted from whooping-cough, four from "fever," four from diarrhœa, one from scarlet fever, and one from diphtheria. These 16 deaths were equal to an annual rate of 2·4 per 1000, the zymotic death-rate during the same period being 1·4 in London and 1·5 in Edinburgh. The fatal cases of whooping-cough, which had been four and seven in the two preceding weeks, declined again to 6 during the week ending Saturday, Dec. 22nd. The mortality both from "fever" and from diarrhœa exceeded that recorded in the preceding week. The 172 deaths in Dublin during the week under notice included 32 of infants under one year of age and 41 of persons aged upwards of 60 years; the deaths of infants exceeded the number in the preceding week, while those of elderly persons showed a decline. Eight inquest cases and six deaths from violence were registered, and 56, or nearly one-third, of the deaths occurred in public institutions. The causes of eight, or nearly 5 per cent., of the deaths in the city during the week were not certified.

The annual rate of mortality in Dublin, which had been 27·4, 25·8, and 25·7 per 1000 in the three preceding weeks, further declined to 21·5 during the week ending Dec. 29th, 1900. During the 13 weeks of the quarter ending Saturday last the death-rate in the city averaged 24·5 per 1000, the rate during the same period being 16·5 in London and 17·6 in Edinburgh. The 144 deaths belonging to Dublin registered during the week under notice were 28 less than the number in the preceding week and included 12 which were referred to the principal zymotic diseases, against 11, 12, and 16 in the three preceding weeks; of these, five resulted from whooping-cough, four from "fever," two from diarrhœa, and one from scarlet fever. These 12 deaths were equal to an annual rate of 1·8 per 1000, the zymotic death-rate during the same period being 1·4 in London and 0·9 in Edinburgh. The deaths referred to whooping-cough, which had been seven and six in the two preceding weeks, further declined last week to five. The four fatal cases of "fever" corresponded with the number in the preceding week. The deaths from diarrhœa, which had been two and four in the two preceding weeks, declined again to two last week. The 144 deaths in Dublin last week included 20 of infants under one year of age and 47 of persons aged upwards of 60 years; the deaths of infants showed a marked decline, while those of elderly persons slightly exceeded the number in the preceding week. Five inquest cases and four deaths from violence were registered, and 53, or more than a third, of the deaths occurred in public institutions. The causes of six, or more than 4 per cent., of the deaths in the city last week were not certified.

THE SERVICES.

THE RETURN OF THE FIELD-MARSHAL.

FIELD-MARSHAL LORD ROBERTS, for so, we suppose, we must continue to call him until the official conferment of the higher titles he has won, landed at Cowes on Jan. 2nd. Here he was received by all classes from Royalty downwards with that respect and affection which he so well deserves. At the landing stage he was greeted by the Duke of Connaught and Princess Henry of Battenberg, both of whom shook his hand in welcome. Owing to the injury received at Johannesberg Lord Roberts was unable to use his right hand, but he was looking in the best of health and had apparently quite recovered from the fatigues of campaigning. Opposite the town-hall of East Cowes there was a grand stand erected for the accommodation of the spectators, while in front of the stand were drawn up five invalid soldiers from South Africa and veterans from various campaigns in which Lord Roberts had taken part. Here were men from Kabul and Kandahar, from Cawnpoore and Lucknow, all come to welcome their chief on his return from his latest and perhaps most arduous campaign, and for all there was a shake of the hand and a kindly word. Addresses were presented from various local bodies, and then Lord Roberts made his speech of thanks—one of those kindly, simple speeches which he so well knows how to make. He thanked them all for the honour done to him and then passed on to consider the state of affairs in South Africa. In his successor in command, Lord Kitchener, he professed absolute confidence, though that commander had no easy task. His lordship continued:—

You, ladies and gentlemen, have been so fully kept informed by the daily telegrams and the newspaper correspondents of the sufferings so nobly borne and the deeds so gallantly done throughout the campaign that I am sure you will not be surprised if I take this, my earliest, opportunity of expressing my pride in having had the command of such a magnificent army—an army composed of men drawn from all parts of Her Majesty's dominions—men of whom the empire and their friends may well be proud. Among them an admirable spirit of camaraderie has ever existed. The soldiers of Great Britain and the soldiers of Greater Britain have pulled together as brothers fighting under one common flag, and owing allegiance to one common Sovereign, who is beloved and revered equally by all. These unanimous outbursts of loyalty must, I think, be extremely gratifying to Her Majesty and must be considered eminently satisfactory by all Her Majesty's loyal subjects, for with our empire firmly knit together we need fear no

outward foe so long as we are careful ourselves to see that there is no weak point in our armour. I thank you all again most sincerely for the great honour you have done me.

Lord Roberts then drove off to Osborne, arriving at the gates punctually at five minutes to four. His bodyguard consisted of his six Indian orderlies, the route being kept by regulars and volunteers, while the carriage was preceded by a squadron of Yeomanry. The Field-Marshal entered by the Queen's entrance and was met in the courtyard by the gentlemen of the household and escorted to the council chamber, where he was greeted by Prince and Princess Christian, Princess Henry of Battenberg, the Duchess of Connaught, and various other members of the Royal family. Shortly afterwards Lord Roberts was received by Her Majesty in private audience, when it was understood that the Queen intimated her intention of conferring an earldom upon him together with the Most noble Order of the Garter. After the audience Lord Roberts left for Southampton and on the morning of Jan. 3rd proceeded to London, arriving at Paddington at 1 P.M. At the station his lordship was met by the Prince and Princess of Wales, the Duke and Duchess of York, and the Duke and Duchess of Connaught. The Queen's route was taken to Buckingham Palace, where at the moment of writing Lord Roberts is lunching.

We express our pleasure at seeing safe home again one who at a time of bitter sorrow put aside his own grief and went at his country's call to bear the hardships and anxieties of a campaign. His work is known to all: let us welcome him in all thankfulness, although by no means forgetting those who are still bearing the burden of empire.

ROYAL NAVY MEDICAL SERVICE.

The following appointments are notified:—Staff Surgeon J. H. Stenhouse to the *Diana*. Surgeons: H. W. B. Shewell to the *Diana*; R. Hughes to the *Arrogant*; R. L. Price to the Royal Marine Division, Portsmouth; M. Breton to the *Vivid*; C. G. Matthew to the *President*; J. G. Corry to the *Duke of Wellington*; F. C. B. Gittings to the *Monarch* for service on ship and Naval Prison; and G. M. O. Richards to the *Mars*.

ROYAL ARMY MEDICAL CORPS.

The undermentioned civil surgeons now serving in South Africa to be Lieutenants:—Walter James Waters, Basil Pares, Henry Francis Shea, Charles Elphinstone Fleming, Percival James Bodington, Joseph Francis Whelan, Percy Samuel Lelean, James Barkley, William Henry Odlum, Frederick Archer Stephens, Miles George Sterling, William Moroney Power, John Tyrer Johnson, Edgar Francis L'Estrange, Robert Barclay Black, and William Morehead McFarlan.

Temporary Captain Thomas Barton Unwin from medical officer, the Imperial Yeomanry, to be Lieutenant.

INDIA AND THE INDIAN MEDICAL SERVICES.

On relinquishing charge of the civil medical duties of the Amritsar District, Captain A. W. T. Buist, civil surgeon, is posted to Gurdaspur as plague medical officer. Lieutenant-Colonel J. Crofts has been appointed surgeon to his Highness the Maharaja of Jodpore.

The Queen has approved of the following promotions among the officers of the Indian Medical Service. To be Colonel: Lieutenant-Colonel James Sutherland Wilkins, D.S.O., Bombay Establishment. Majors to be Lieutenant-Colonels: Bengal Establishment: George Michael James Giles, Arthur Robert Wyatt Sedgefield, Edwin Francis Horatio Dobson, Johnston Shearer, D.S.O., Hem Chandra Banerji, Sambhu Chandra Nandi, and Francis Samuel Peck. Madras Establishment: John Lawrence Van Geyzel, Hastings Norman Victor Harington, Gerard Macklin Eccles McKee, Kavasji Cursetji Sanjana, Hormasji Merwanji Hakim, John Adolphus Burton, Francis Joseph Doyle, Manekshaw Jamshedji Kelá wálá, and Mervanji Pestanji Kharegat. Bombay Establishment: Kavasji Hormasji Mistri, George Ernest Fooks, and Joseph William Townsend Anderson. Captains to be Majors: Bengal Establishment: Herbert Edward Drake-Brockman, William Byam Lane, and Philip James Lumsden. Bombay Establishment: Samuel Esmond Prall.

ROYAL MALTA ARTILLERY.

Surgeon-Lieutenant Robert Vella, from the Royal Malta Regiment of Militia, to be Surgeon-Lieutenant (with local and temporary rank).

ARMY MEDICAL RESERVE OF OFFICERS.

Surgeon-Major J. P. Massingham resigns his commission.

VOLUNTEER CORPS.

Artillery: 1st Norfolk (Eastern Division, Royal Garrison Artillery): Surgeon-Lieutenant John Charles Reynolds Robinson resigns his commission and is appointed Second Lieutenant. *Rifle:* 1st Volunteer Battalion the Royal Fusiliers (City of London Regiment): Brigade-Surgeon-Lieutenant-Colonel S. P. Smith resigns his commission, with permission to retain his rank and to wear the uniform of the battalion on retirement. 3rd Volunteer Battalion the South Staffordshire Regiment: Supernumerary Surgeon-Captain C. A. MacMunn to be Surgeon-Captain on the Establishment. 4th (Perthshire) Volunteer Battalion the Black Watch (Royal Highlanders): Surgeon-Lieutenant Colonel J. Macfee resigns his commission, with permission to retain his rank and to wear the uniform of the battalion on retirement. 1st (Renfrewshire) Volunteer Battalion, Princess Louise's (Argyll and Sutherland Highlanders): The undermentioned officer resigns his commission: Surgeon-Lieutenant C. McBryde. 20th Middlesex (Artists'): Surgeon-Lieutenant C. S. de Segundo to be Surgeon-Captain.

ROYAL NAVAL HOSPITAL, HASLAR.

The session of instruction at the Royal Naval Hospital, Haslar, for newly-entered surgeons in the Royal Navy terminated on Dec. 21st, 1900, when the prizes were distributed by Sir Henry Norbury, M.D., K.C.B., Director-General of the Medical Department of the Navy, and they were awarded as follows—viz., two prizes consisting of a gold medal and a microscope to Surgeon George Ross, B.A., M.B., and one prize, a silver medal and books, to Surgeon Noel H. Harris.

The following is a list of the surgeons who have been under instruction during the session, arranged in order of seniority as determined by the sum total of the marks obtained at the examination in London on entry and those on the conclusion of the Haslar course:—

Name.	Marks.	Name.	Marks.
G. Ross, B.A., M.B. ...	6360	J. M. H. Conway	4348
J. S. Dudding	5407	H. V. Wells	4341
N. H. Harris	5133	W. Bastian...	4254
H. C. Adams	4975	R. B. Scribner	3965
L. Lindorp...	4960	A. J. Sheldon	3673
C. T. Baxter	4922	J. Verdon	3486
W. E. Gribbell	4622	J. Whelan	3466
R. W. B. Hall	4421	C. R. Rickard	3347

MAUSER WOUNDS AND AMPUTATION.

Writing on this subject in a recent number of the *Archives de Médecine et de Pharmacie Militaires*[1] Dr. J. Alvernhe expresses himself to the following effect. During the early months of the South African war the whole of the surgeons engaged had the satisfaction of noting how relatively benign the wounds that were caused by Mauser projectiles showed themselves, rarely necessitating any serious operative intervention. Consequent on reports from such eminent surgeons as Sir William Mac Cormac, Mr. Treves, and Mr. Dent, the notions became widely current that Mauser bullets generally passed clean through bones, making small cylindrical channels which looked as if they had been cut out by a punch; that penetrating wounds of the cranium were, for the most part, attended by merely insignificant disorder; and that the new projectile threaded its way amidst vessels and nerves without giving rise to any immediate or subsequent disturbance of a grave character. Later, however, the conditions to which these favourable results were due seem to have undergone considerable modification, and the surgeons who ached the theatre of war during the second stage of the campaign were unable to emulate the optimism of their predecessors. Equally ardent exponents of conservative surgery, these distinguished men frequently found themselves reluctantly compelled to have recourse to amputation in order to save the lives of patients for whose injuries the Mauser rifle was responsible. Many reasons have been advanced to account for this regrettable alteration of type. In the first place, it is said that the Boers of late have taken to manipulating their cartridges in order to make the bullets spread on impact and in this way to inflict

[1] No. 12, December, 1900, p. 514.

a wide, ragged, and excessively serious wound instead of the smooth, narrow burrow as above described. Secondly, in the opinion of some observers the space between the combatants has tended to grow less than it was at first, and as a natural consequence the severity of the wounds received at the shortened ranges is much greater than it was. In the third place—and according to Dr. Alvernhe it is here that we have to look for the real explanation—the soldiers being all more or less worn out owing to climate, exposure, bad food, privation, and excessive marching are not so apt for recuperation as they were at the beginning of the war. Their constitutions have run down and their wounds consequently suffer from the lack of vitality. Hence the frequency of the suppurations which are now found to retard cicatrisation.

TRANSVAAL WAR NOTES.

Major B. W. C. Deeble, R.A.M.C., and Civil Surgeon H. J. Starling left South Africa for England in the *Dunera* on Christmas Day.

The following have been discharged from hospital to duty:—Civil Surgeons: H. E. Birmingham, W. O. Beddard, W. J. Collins, and A. Thompson.

SOME FACTS RELATING TO CHOLERA IN INDIA.

The annual report for 1898 of the Sanitary Commissioner with the Government of India published recently contains, among other things, some interesting facts in connexion with cholera. The year 1898 was a relatively healthy one both as regards the European and native armies of India and the native population, and the military shared in the immunity from cholera—an immunity which generally existed throughout the Indian Empire. Cholera occurred among British troops in nine stations only, and there were in all 30 cases and 21 deaths, a case-mortality of 70 per cent. In only one instance was the disease in epidemic form—viz., at Umballa, where there were 20 seizures, with 10 deaths out of the 11 Europeans attacked. Among native troops cholera occurred in six stations among 10 bodies of men. There were in all 57 cases, of which 44 ended in death, a case-mortality of 77·2 per cent. Only 11 jails out of the total number of Indian jails suffered, and there were only 18 cases in all. From the cases in which details were available it appears that altogether 259 individuals were in attendance on 102 cholera cases, and none of them were attacked. No seizures followed subsequently to the movement of troops from infected localities in the case of British troops, but the effect of such movement, although generally satisfactory, was not so completely successful in the case of native troops. The outbreak among European and native troops and followers at Umballa was of special interest, because the Punjab was apparently free from cholera at the time of its occurrence. It is unfortunate, however, that the accounts of the outbreak at Umballa were of a fragmentary character. The Umballa cantonment water-supply is conveyed by pipes which were leaky, and the medical officers consequently ascribed the outbreak to a polluted water-supply, but there was no satisfactory evidence pointing to the water as the cause of cholera. It is curious "that the vibrio of cholera was found in the well used by the Government model dairy, but no case occurred at the dairy, and neither the milk nor the butter from the dairy, appear to have been used by the natives who suffered."

THE STORY OF THE THORN.

The story of the thorn is published in the *Times* of Dec. 26th, 1900, as illustrative, we suppose, of the surgical incompetence of the medical staff and the shortcomings of army hospitals in South Africa. It may or may not be an accurate record of the experience of the patient in question, about which we have our own opinion. But it seems to us grossly unfair and wrong for a writer to seek to cast a slur upon a body of men belonging to any service under the shelter of anonymity. "F.R.C.S." may have a keen appreciation of what constitutes a good story, but we cannot congratulate him on any fastidious sense of honour or justice. If he considered it his duty on public grounds that the allegations should be brought to notice he could easily have done this through the proper channel. At any rate, the story should not have been told anonymously but should have been signed and accompanied by such particulars as would have enabled the authorities on the spot to have instituted, in the interest of all concerned, some inquiries into the matter. As it is, "F.R.C.S.," has cast an unworthy aspersion indiscriminately upon a large number of members of his own profession in the army and, in effect and by implication, has maligned them.

ARMY REFORM.

It is understood that Lord Wolseley will take an early opportunity of speaking on this subject in the House of Lords, and there is naturally a good deal of interest and curiosity felt as to what the late Commander-in-Chief will have to say and as to the nature of the reply which the Government will make and the course which it will adopt. The matter is one of national interest and concerns the medical as well as all other branches of the army.

On Jan. 1st Her Majesty the Queen paid a visit to the Convalescent Home at East Cowes. Several men from South Africa were there, and on the evening of the same day members of the Royal family from Osborne entertained them with music, both vocal and instrumental.

Among the names in the list of New Year honours is that of Major John Crimmin, I.M.S., V.C., who has been made a Companion of the Order of the Indian Empire.

Correspondence.

"Audi alteram partem."

LENGTHENING TENDONS FOR THE SO-CALLED ISCHÆMIC PARALYSIS (VOLKMANN) FOLLOWING ON INJURIES ABOUT THE ELBOW-JOINT.

To the Editors of THE LANCET.

SIRS,—In your review of the surgical work of the year you refer to tendon lengthening as one of the surgical procedures worthy of note. The case you refer to is "a little boy suffering from ischæmic paralysis the result of application of splints for a fracture of the lower end of the humerus or separation of the lower epiphysis of the humerus." In THE LANCET of Feb. 3rd, 1900, you kindly published a clinical lecture of mine on this subject, and if you will allow me I should like to again emphasise one or two points I then raised.

I think it is extremely unfortunate that such an inappropriate term as "ischæmic paralysis" should be applied to a condition which is really primarily a contraction of muscles and not due in any way to the involvement of the nerves, nor can it be shown to be the result of deprivation of blood to the parts—ischæmia. In my lecture I stated:—

> The deformity appears always to occur in children after some severe injury about the elbow-joint and generally after a fracture separation of the lower humeral epiphysis. I have once seen it after a dislocation of both bones of the forearm backwards. The cause of the deformity is, I believe, primarily in the muscular portions of the flexor muscles of the forearm. If the histories of these cases are carefully gone into it will be found that the injuries have been severe and that the flexor muscles have been torn, possibly by the displacement of the forearm backwards with the lower end of the humerus. The torn muscle is replaced by fibrous tissue, and this contracting is, I believe, responsible for the deformity. A lump varying in size can be felt in the flexor muscles in the upper third of the forearm and it has been present in all the cases which I have seen. It is a well-recognised condition in the sterno-mastoid muscle. A swelling is found in about the middle of the muscle soon after birth, which is thought to be due to a tearing of its fibres during parturition; this sometimes produces wry-neck.
>
> I do not believe that splint-pressure has anything to do with the production of the deformity, although I am well aware that in most cases a sore—pressure sore—is present; but this is not always so, for in Case 1 no abrasion of any kind was present and in Case 2 a sore formed but was on the extensor surface of the forearm. I am especially laying stress on this point as it has given rise to one theory—that the contraction is due to a secondary inflammation extending to the muscles from the splint sore. That explanation clearly will not account for Case 1 in which there was no sore of any kind, and in Case 2 the sore was on the back of the forearm. One would imagine that any inflammation extending from this sore would have involved the extensor muscles and produced a hyper-extension of the wrist instead of involving the flexor muscles. For these reasons I am inclined to think that the pressure-sores are not causally related to the deformity; they may, however, be taken as some index of the amount of laceration of the soft parts at the time of the injury, producing a great amount of effusion which increases in amount after the application of splints. Probably the effusion of blood into the skin and subcutaneous tissues renders them anæsthetic, acting in the same way as a hypodermic injection of water; and this may explain why a large sore may form and yet the patient will not complain of any pain.

The explanation here given is, I venture to think, worthy of a fuller consideration. As to the treatment by tendon

lengthening the results justify the treatment. Mr. Page and myself quite independently arrived at the same conclusion that this was the most reasonable way of treating this particular deformity. By referring to the records of our cases it will be seen that I performed the operation about a month before Mr. Page—another example of arriving at the same conclusion independently when similar conditions are under consideration. In my first case the result is now excellent; in the second case the result is fair, the fingers are straight, but the movements are weak. I have since operated on a third case, on August 28th, 1900—a girl aged three years. Her fingers are now quite straight and the power is daily improving; it is too early yet to speak of what the ultimate result will be.—I am, Sirs, yours faithfully,

Leeds, Dec. 31st, 1900. H. LITTLEWOOD.

"ARSENIC IN ARTIFICIAL MANURES."

To the Editors of THE LANCET.

SIRS,—THE LANCET of Dec. 22nd contains a short annotation under the above heading which, if copied into numerous country papers, is calculated to produce a most unwarrantable prejudice against the application of artificial manures. It is not sufficient to make general statements, the actual facts should be given. If, as the writer of the annotation states, "the results are not yet ripe for publication," why should a premature prejudice be created in the public mind? In one paragraph it is stated that the Laboratory Commissioners had found certain artificial manures to be rich in arsenic in a soluble form—namely, soluble in water; but further on in another paragraph it is suggested that arsenic accumulates in the soil. Now, if arsenic be present in a form readily soluble in water it must be obvious that it is not likely to accumulate in the soil. On the contrary, if it exists in a soluble form it is more likely to be washed out of the soil than to accumulate. The mere presence of arsenic in a sample of artificial manure is no evidence whatever that crops manured with such a fertiliser would be in any way likely to produce injurious results to the health either of man or beast. In all these matters it is a question of quantity. Some years ago the present writer had occasion to examine some meadow grass which was rendered unfit for grazing purposes in consequence of sediment deposited from the washings of a copper mine, and in order to make a comparison of the amount of copper salts present pieces of turf were obtained from portions of the field not damaged by mineral washings, but, curiously to relate, these pieces of turf contained appreciable quantities of copper, and the grass had been evidently appreciated by the cattle who had refused to eat the portion upon which the detrita of the mine washings had been deposited. The quantity of arsenic likely to be supplied in any artificial manure must be exceedingly small when distributed over the whole field, probably not more than $\frac{1}{10}$th of a grain per square foot, and being in a soluble form is quite as liable to be washed out of the soil as to be absorbed by turnips or cabbages. I am, Sirs, yours faithfully,

Mark-lane, E.C., Dec. 31st, 1900. JOHN HUGHES, F.I.C.

*** Our words "the results are not yet ripe for publication" did not refer to the examination of artificial manures but to an investigation into other substances. A list of these will be found in another column of this issue (see p. 54). The fate of soluble arsenic, according to our correspondent's view, would be precisely the same as that of the equally soluble nitrates and phosphates used for fertilising purposes. Are they also "washed out"?—ED. L.

"ISOLATION HOSPITALS."

To the Editors of THE LANCET.

SIRS,—The following cases occurring during the past week are surely a proof of Mr. E. D. Marriott's contention that the "return" cases from isolation hospitals are probably the greatest source of further infection. Two children, William Neville and Annie Foster of Henham, Essex, living about two miles apart, returned from the Hospital for Infectious Diseases at Bishop's Stortford on Dec. 16th last. William Neville was sent there on Oct. 22nd and Annie Foster on Nov. 2nd, both suffering from scarlet fever. The child Neville was kept longer than the usual six weeks so that they "might return home together." Their respective homes were absolutely free from any disease during the time that the children were in hospital, but on Dec. 23rd, just a week after the return of each, I discovered a fresh outbreak of scarlet fever in both of the homes, two children being attacked in Neville's house and one in Foster's. The child Neville had a nasal discharge when he returned home.

As far as I can ascertain these were the only cases of scarlet fever in the near neighbourhood. So there is certainly no doubt whatever that these "return" cases were the cause of the second outbreak. My idea is that isolation hospitals should be situated on eminences, if possible, as far away from the town as practicable and an intermediary home or hospital (at a distance) should be supplied where convalescents could remain for a further fortnight after discharge from the isolation hospital and where they should be daily bathed, sent out in the open air, and examined and returned to their homes either in new clothes or properly boiled old ones. I am, Sirs, your faithfully,

Stansted, Essex, Jan. 2nd, 1901. EDGAR PITTWAY.

"THE TEACHING OF ANÆSTHETICS."

To the Editors of THE LANCET.

SIRS,—THE LANCET of Nov. 17th, 1900, contains a leading article (p. 1440) and a letter (p. 1460) by a well-known surgeon—Mr. J. Lionel Stretton—on anæsthetics. Mr. Stretton complains that "such recently qualified men as seek for hospital appointments are lamentably ignorant in the administration of anæsthetics," and this being the case with the pick of the men entering the profession "the rank-and-file must be deplorably incompetent." Mr. Stretton further states that the "examining bodies do not demand any special training in this important subject. ..... I hope the General Medical Council will give their early attention to the matter." The leading article adds point to Mr. Stretton's remarks, and makes it tolerably clear that the principal reason for his complaint is to be found in the fear of chloroform which is impressed upon students by the teaching of anæsthetics in London. We are told by the writer of the article that the safety of an anæsthetic depends, not on the method of administration, but on "whether or not its power of destroying nerve protoplasm is great or small. That of chloroform is great, that of ether is slight, that of nitrous oxide is least of all." This antiquated doctrine is destitute of the smallest shred of truth, as chloroform and ether when inhaled have no more effect on nerve protoplasm than they have on the protoplasm of the stomach or the biceps. But the moral of such teaching, of course, is that the use of chloroform, the most beneficent of all anæsthetics, should be restricted to the narrowest limits, and in dental operations, at all events, only gas or gas and ether employed. As long as fustian of this kind constitutes the standard teaching in England it is useless to expect any improvement whatever in the confidence and ability of the rank and file of the profession to administer anæsthetics. Nor would examinations improve the matter, since they would only test the proficiency of the student in the teaching which is at the root of the evil. The effects of this teaching, which has been tolerated a great deal too long, are threefold. It has rendered the anæsthetist inefficient—chiefly through fright; it has been the direct cause of an immense number of preventable deaths; and it has tended to debase surgery.

In THE LANCET of the previous week (p. 1383) Dr. Dudley Buxton, who is an authority on the London methods of teaching anæsthetics, states that the anæsthetist is not to be looked upon "as a giver of an anæsthetic. His familiarity with surgery should enable him to know what the operator requires, and what will be the effect of the operator's manipulations upon the patient under anæsthesia. His knowledge of anæsthetics should be such that he can adapt the anæsthetic to the necessities of the patient and the requirements of the surgeon. The tremendous responsibility of the anæsthetist whose want of knowledge, of skill, or of courage may jeopardise the patient's life or frustrate the surgeon's most skilful endeavours should be most fully recognised." The first part of this statement appears to be tantamount to advising the man who is giving chloroform to devote part of his attention, the whole of which ought to be concentrated on the inhalation, to assisting or furthering in some way or other, or "keeping

an eye on," the manipulations of the surgeon, and if this is Dr. Buxton's meaning it cannot be too strongly condemned, as it is acknowledged to be the most dangerous of all doctrines to preach. But the gist of the whole argument is more fully disclosed in the second part of the statement. It is that the surgeon is no longer to be responsible for the safety of his patient, but the responsibility is to be shared by the man who gives the chloroform or ether. In certain eventualities the anæsthetist is to dictate to the surgeon, so that the surgeon becomes a mere operator, a subordinate instead of the chief who under all circumstances retains the supreme command and the entire responsibility in his own hands. This constitutes in my opinion the tendency to the degradation of surgery against which surgeons should guard with all their might. There is no doubt about its evil effects on the profession. I know of an operation in England where the anæsthetist gave the patient a slight overdose of chloroform with a Junker's inhaler. The patient, a child, became pallid, and the anæsthetist told the surgeon that he must stop the operation as there was some shock. The surgeon meekly obeyed this direction and sent the child back to bed with the operation unfinished. The proper course for the surgeon obviously was that he should have noticed that the chloroform was being given a little too freely and have told the anæsthetist not to give so much.

The writer of the article of Nov. 17th sheds crocodile tears over the "potency" of chloroform, a phrase which must mean one of two things: either (1) it means that the rank and file of our profession are not to be trusted to employ a potent drug—e.g., chloroform—with safety; or (2) that chloroform possesses a special potency for evil of its own. No one, least of all THE LANCET, could insult the profession by attempting for a moment to maintain the first of these propositions, which is belied in practice in the case of other drugs quite as potent as chloroform every day, and the second is only true in so far as faulty and unsafe methods of administration are concerned. Chloroform has no particular or mysterious potency or action of its own apart from overdosing, and overdosing can be avoided by anybody who knows how to look after the breathing in the right way. I would venture to urge that if THE LANCET, instead of using its enormous power to restrict the employment of chloroform, adopted the opposite tactics and exerted all its influence to extend the benefit of the anæsthetic it would be doing the profession a service of the greatest possible magnitude, which it would be impossible to repay. Snow's obsolete methods and teaching have had a fair and extended trial, with the result that of the men who pass out from the English schools the best are said to be "lamentably ignorant" and the rank and file "deplorably incompetent" in the administration of anæsthetics. Let Syme's principles and the Hyderabad method of administration of chloroform now have an equally fair trial and the entire position of anæsthetics will be changed. I am convinced from careful observation that the students of the London medical schools, judging especially by the young men who are entering the services in India, are unsurpassed anywhere, and if properly instructed are capable of giving chloroform with absolute safety. Here we use chloroform for everything, and as a rule we never even extract a tooth, in hospital or private practice, without it, and none of our patients, as far as I am aware, ever runs the smallest risk. It would be absurd to contend that what we do daily in routine practice the men of the English schools cannot do at all. So long, however, as they are controlled and hampered by an unfounded fear of chloroform anæsthetics will remain in their present unsatisfactory state, and surgery will continue subjected to the degrading and throttling thraldom of ether.

I am, Sirs, yours faithfully,

E. LAWRIE, M.B. Edin.,
Lieutenant-Colonel I.M.S., Residency Surgeon,
Hyderabad (Deccan).

Dec. 10th, 1900.

THE DRINKING OF METHYLATED SPIRIT.

To the Editors of THE LANCET.

SIRS,—May I be permitted to draw attention to the ravages which the drinking of methylated spirit, now indulged in to an enormous extent by the poorer classes of all the great towns, brings about amongst its victims. I would also suggest that the time is now opportune to investigate its pathology, and its more characteristic clinical manifestations. Methylated spirit, as now allowed to be sold by the Inland Revenue, consists of about 88 per cent. of alcohol, 62 over proof, 10 per cent. of wood naphtha, and about 1 per cent. of petroleum oil. The addition of the mineral oil was expressly added with a view to prevent its being drunk, but spirit-takers soon discovered that by adding water to the spirit the petroleum oil was separated and could be removed. It generally retails at from 5*d.* to 6*d.* per pint and, containing as it does twice as much alcohol as the best whisky, the drinker is enabled to procure the alcoholic equivalent of half a pint of whisky for three-halfpence. It is quite obvious, then, that the one thing needful in order to obtain an unlimited supply of alcohol for a few pence daily is to acquire a taste for the poisonous spirit, and this is apparently readily cultivated, especially by those who have long learned to seek in spirit a stimulant and not a bouquet.

Cases, although they are numerous enough, where death has followed the use of methylated spirit have usually been classed as due to some form of alcoholism, and even men of considerable experience may be found to deny that they have ever known of a fatal case, short of a history of the habits of the individual. I do not know of any post-mortem signs which would indicate that the methylated and not ordinary alcohol had been used, but the wood naphtha seems to affect the spleen more than is common in cases of mere alcoholism, and the blood seems to stain the serous membranes, as is found after many poisons. The heart muscle seems to become darkened and very friable, and the tendency to general arterio-fibrosis is apparent at a much earlier age than obtains even with alcoholics. Takers of methylated spirit deny the habit with a persistency and an ingenuity which are only equalled by those of a cocainomaniac, and which are infinitely more acute than the excuses of the opium-drinker, whose habits are generally marked on his person. They differ, too, from the mere drunkard in this, that but a small quantity can be taken at a time, and the effects pass away quickly—phenomena which have been already noted in the case of ether-drinkers. Many of the victims are poor students and literary hacks, and unlike purer alcohols methylated spirit does not seem so prone to produce somnolence. The impossibility of early morning sleep and the craving for the spirit with the break of day are marked characteristics, but instead of being heavy, sodden, blear-eyed, stupid, and sick, the victims, even in the earliest morning, are bright, keen, intelligent, active, yet with a yearning for the spirit which might be described rather as a hunger than a thirst. As methylated-spirit-drinking is indulged in to the extent of probably 100,000 gallons per annum, and has doubtless caused infinitely more deaths than arsenical beer, it might be fitting that it should receive some notice at your hands.

I am, Sirs, yours faithfully,

J. C. MCWALTER, B.A., D.P.H., F.F.P.S.

Dublin, Dec. 26th, 1900.

"SOME DISAPPOINTMENTS IN SURGERY."

To the Editors of THE LANCET.

SIRS,—May I add a few remarks to those of Mr. D'Arcy Power in reference to "mental disturbance following a surgical operation" in his interesting paper on Some Disappointments in Surgery in THE LANCET of Dec. 22nd (p. 1789)? It seems to me that none of the three cases he cites from his personal experience is an instance of "post-operative insanity," strictly speaking. His first is "pre-operative," so far as the report shows. The second is most likely "post-anæsthetic," and the third was probably also toxic and septic. In classifying cases, I think those whose "mental condition is clearly impaired from the time of recovery from the anæsthetic," and also those who are evidently septic, should be differentiated from "post-operative" cases pure and simple, in which so far as can be ascertained, the mental disturbance is not due to either the anæsthetic or a septic condition. Sir W. M. Banks and Dr. Macphail have both referred in their recent papers to an article of mine on Post operative Insanity in the *Journal of Mental Science* for January, 1897. The points relating to the action of anæsthetics, sepsis, &c., are, however, more fully discussed in "Cerebral and Mental Symptoms," from which book the article noted was largely taken.

I am, Sirs, yours faithfully.

Cambridge, Jan. 1st, 1901. J. CHRISTIAN SIMPSON.

A POINT IN THE ADMINISTRATION OF NITROUS OXIDE GAS.

To the Editors of THE LANCET.

SIRS,—May I ask for a small space in your columns to try to eliminate during the present century the uncomfortable and pernicious habit of advising a patient "to breathe deeply," "to take a deep breath," "to breathe as if you were blowing on a looking-glass," &c., which has been employed ever since nitrous oxide insensibility has been induced, and seems likely to be with us always. Such a method is perfectly unnecessary, is very disturbing to the patient, and is very much in the way of a comfortable insensibility. I have tried to prevent patients from thinking of their breathing for nearly 40 years, but it happens so often that the patient has been so instructed that I beg once more to call attention to it as at least undesirable and due to want of thought.

I am, Sirs, yours faithfully,

Brook-street, W., Jan. 1st, 1901. TOM BIRD.

"THE TREATMENT OF PULMONARY TUBERCULOSIS."

To the Editors of THE LANCET.

SIRS,—Having read with much interest, and I trust with profit, Dr. Robert Maguire's interesting lectures on the above subject I am delighted to agree with his incisive criticism in a great many particulars. It is time some counterblast was raised against the numerous sanatoria springing up like mushrooms all over the country, the main idea being speculation and the well-being or recovery of the inmates quite a secondary consideration. In this connexion it would be interesting to inquire how many cases are accepted for treatment who are not genuine cases of tuberculosis but who are perhaps allowed to live in that idea and others buoyed up into the false hope of cure who are quite beyond human aid.

No wonder Dr. Maguire makes the remark: "The profession seems to have gone mad on this matter." But it is to be hoped there are some exceptions to this sweeping statement. We all remember the Koch "cure" and the numbers of the profession who rushed to Germany to annex the idea come home and at once float into fame. We know the result, and the open-air treatment will in a short time die, as it has done when tried before. The instance of forced feeding by mutton chops *ad nauseam* will probably be improved upon by mechanical aids, something after the manner of feeding turkeys and cramming fowl. The patient instanced by Dr. Maguire no doubt paid well for his chops but gave a bad return. It would be nearly as sensible to treat juvenile "consumption" with stale bread.

I am, Sirs, yours faithfully,

Dec. 31st, 1900. M.R.C.S.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

Plague and the Mecca Pilgrimage.—The Benefit to Ceylon of Plague Regulations.—The Epidemic at a Standstill.—The Mortality of the Great Famine.—The Bacillus of Beri-beri.

NOTWITHSTANDING that the European Governments, including that of Turkey, realise the danger of importing plague the Government of India do not think it necessary to prohibit pilgrimage from the unaffected portions of India during the ensuing season. It is said that the Indian pilgrims during last season were subjected at Turkish ports to many vexatious restrictions and consequent hardships, but the Government of India consider it essential that careful precautions should be observed at Indian ports similar to those which were enforced during the past season. Accordingly, the port of Karachi for pilgrims from parts of the north of India and the port of Chittagong for other parts have been determined as the only places where pilgrims may embark for the Haj. No person will be permitted to make a pilgrimage to Mecca this season from any of the infected portions of India—viz., the Presidency of Bombay excluding Sind, the Madras Presidency, the Mysore State, Coorg, the Jullundur District of the Punjab, and Bengal, excepting the Chittagong division.

Ceylon has been peculiarly free from cholera during the past year. The explanation appears to be the following. All outbreaks of cholera can be traced to India and must be introduced, as cholera does not occur spontaneously. The north road coolie route was closed to coolie traffic on Jan. 1st, 1899, in order to guard against plague, but it appears to have had the additional advantage of keeping out cholera. The coolies in former years had to march some 130 miles to their places of employment along the north road, and by the time that they arrived they were generally in such a depressed condition that they readily succumbed to any disease to which they were exposed. Now the coolies have to come straight from the port of embarkation to Colombo and are at once fed and cleansed and then sent to the Ragama camp. On the next day they are sent by train to their destination.

The plague returns for India show little change. There were 1889 deaths for the week ending Dec. 8th, as compared with 2140 deaths for the previous seven days and with 1579 for the corresponding week of 1899. The Bombay Presidency reports a decline from 560 to 329 deaths, and the Mysore State also from 610 to 523 deaths. In Bengal, however, there has been an increase from 798 to 878 deaths, Gaya and Patna and those districts showing the chief development. In Bombay city the returns would make it appear that the plague is about stationary and the same may be said for Calcutta. In both cities, however, there are signs of a recrudescence, more especially in Calcutta where many more suspicious and plague deaths occur than are reported. For the week there were 65 deaths in Calcutta and 70 deaths in Bombay.

Your readers will regret to hear that the Corporation of Bombay have refused to subscribe towards the Pasteur Institute at Kasauli.

The numbers under famine relief have now sunk to about 250,000. Lord Curzon calculates that the famine has cost the parts of India affected about 750,000 lives. As a matter of fact, however, comparatively few died from sheer starvation, although insufficient diet and destitution over a considerable period indirectly caused a large amount of sickness and mortality.

One of the most important communications on the subject of beri-beri appears in the Indian Medical Service paper for December. Captain E. R. Rost, I.M.S., of Burma describes a diplo-bacillus which forms a sort of angle. He has been working on the idea that beri-beri is a rice disease and has found the organism between the starch cells. Several kinds of fermented rice-water are used by the natives and a peculiar yeast which is obtained from Singapore is used to produce them. Captain Rost has also found the same peculiar organism in the blood of beri-beri patients in the cerebro-spinal fluid, and in the serous exudation of the sheath of the sciatic nerve. The organism develops spores and is very active—"wagging one rod in front of the other." In 32 cases of beri-beri the organism was found in every one. It seems to be peculiarly resistant to heat.

Dec. 13th, 1900.

LIVERPOOL.

(FROM OUR OWN CORRESPONDENT.)

The Lord Mayor's Hospitals' Century Fund.

THE Lord Mayor has issued an appeal to the citizens of Liverpool for subscriptions towards a fund which he proposes to call "The Hospitals' Century Fund," with the object of freeing the hospitals from debt. The gross amount of the debit balances of the various hospitals stands at present at about £26,000; and the Lord Mayor is anxious that these adverse balances should be discharged during his year of office, thus enabling the hospitals to commence the century free from debt. The Lord Mayor heads the subscription list with the sum of £200. Already £4039 have been promised towards this laudable object. The Lord Mayor's suggestion is a good one and there is every probability that the requisite amount will be obtained.

Low Death-rate of Liverpool.

At the weekly meeting of the Health Committee of the City Council held on Dec. 27th, 1900, the chairman congratulated Dr. E. W. Hope, the medical officer of health, upon the low death-rate at present prevailing in the city. The death-rate for the past week was equivalent to 18·6 per 1000, as

against 32·1 per 1000 for the corresponding period of 1899. This satisfactory feature in the health of the city is no doubt due to good management and improved sanitation on the part of the health department. 72 deaths took place in public institutions of which 10 were deaths of non-residents. The epidemic of peripheral neuritis still continues in the two workhouses recently alluded to in THE LANCET. I have not heard of any cases having been treated at the general hospitals.

Presentation to the Medical Officer of Health of Rochdale.

At a meeting of the Health Committee of Rochdale Corporation held on Dec. 28th, 1900, Dr. Joseph Henry, J.P., the medical officer of health of Rochdale, was presented by the chairman, on behalf of the members of the committee, with a handsome silver salad bowl on his completing 21 years' service as medical officer of health of the borough. Alderman Hardman, the chairman of the committee, in making the presentation, spoke in cordial terms of the manner in which Dr. Henry had performed his duties as medical officer of health. Some members had been associated with the work of the committee during all the time of Dr. Henry's service, and their esteem for him had grown as the years went on. In accepting the gift Dr. Henry warmly thanked the members of the Health Committee for the kindly thought which prompted the presentation of the gift, which he accepted as a manifestation of the goodwill which existed between the committee and himself. He assured them that he and the members of his family would value the gift as the expression of the good feeling entertained by the committee towards him.

Jan. 1st.

WALES.

(FROM OUR OWN CORRESPONDENT.)

Sanitary Authorities and Water-supplies.

AT the end of 1897 a circular letter was addressed by the Local Government Board to the sanitary authorities in England and Wales directing attention to the subject of the water-supplies of their districts and urging the importance of ascertaining whether the water delivered to consumers was fully protected from all risk of contamination. In many parts of Wales the water-supply is absolutely above suspicion, but in some of the more thickly populated districts epidemics of water-borne typhoid fever are not at all infrequent; yet it is doubtful whether in more than one or two instances any action at all was taken upon the communication from the Local Government Board. In strange contrast to this inertia is the activity displayed by the same authorities upon receipt at the end of 1900 of a circular letter from the Board recommending that samples of beer and other articles of food likely to contain arsenic should be obtained for analysis. Even the County Council of Glamorgan is not exempt from this criticism, for at the last quarterly meeting of this body, when the sanitary committee recommended the appointment of an inspector to act under the direction of the county medical officer of health in procuring evidence of the pollution of water-supplies the recommendation was strenuously and successfully opposed by the chairman of the local government committee, who immediately afterwards proposed that the inspectors under the Food and Drugs Acts be ordered to obtain for analysis samples of beer and of sweets, jam, golden syrup, and canned fruit. This proposition was unanimously carried. The medical officers of health for Cardiff, Rhondda, and Swansea, the three largest towns in Wales, have reported that after investigation they have been unable to obtain evidence either of any cases of sickness due to drinking arsenicated beer or of the presence of arsenic in the beer consumed in their respective localities. In Merthyr and in Blaina, on the other hand, it is reported that suspicious cases have been found of peripheral neuritis which may be associated with beer consumption. In connexion with this subject it is of interest to record that in a newly-erected hotel in Aberdare the pipes along which the beer is drawn from the barrels in the cellar to the beer-engine in the bar are of glass. The pipes rest upon long narrow wooden shelving, and breakages are rare.

A Convalescent Home for Cardiff.

A convalescent home for women and children has recently been established at Cardiff which will relieve somewhat the strain upon the wards of the general infirmary. The building utilised was formerly a private residence and stands in grounds at the outskirts of the town. The entire cost of acquiring the house and of making extensive alterations has been borne by the executors of the late Mr. James Pyke Thompson, and the maintenance of the institution is provided for by the income arising from a sum of money left by him. At present there is only accommodation for 12 patients who will be received without payment. The Cardiff Infirmary is entitled to the use of six beds. Hitherto the Porthcawl Rest was the nearest convalescent home available for Cardiff patients.

An Accident Hospital for Pontypool.

A movement has been started to establish an accident hospital in or near Pontypool to serve the eastern valleys of Monmouthshire, where the need for a properly equipped hospital has long been keenly felt. At a meeting of the promoters it was announced that 7000 workmen had each promised to contribute 1*d.* a week towards the support of the institution.

The Pollution of the Rhymney.

The river Rhymney, which divides Glamorganshire from Monmouthshire, has long been the cause of much concern to the county councils affected. A joint committee of the two councils was established to take united action in preventing pollution of the stream, and as the result of the pressure brought to bear by this committee several districts, notably Caerphilly, Rhymney, and Gelligaer, have been induced to spend considerable sums upon drainage schemes which will result in withdrawing sewage from the Rhymney river and thus lessening the amount of pollution. The work of the committee has been very much hampered because the Monmouthshire County Council declined to delegate to their representatives on the committee their powers under the Rivers Pollution Acts. The Glamorganshire County Council have therefore decided to dissolve the joint committee.

Prayer-meetings at Infected Houses: a Persistent Action in Wales.

At the village of Deri in the parish of Gelligaer, Glamorganshire, an outbreak of diphtheria took place five weeks ago, when five cases, including two deaths, were notified to the medical officer, Dr. W. W. Jones, Merthyr. During the month this number has been increased to 42, including 11 deaths. This abnormal jump caused an investigation to be made, when it was discovered that the people persisted in visiting infected houses, quite disregarding a printed notice prohibiting this wholesale method of spreading the disease. Verbal intimation was given at each house to isolate the premises as far as possible, but the inhabitants were determined to run the gauntlet of all possible risks, and they almost defied the efforts of the officials of the county council to prevent them from calling at any house which was infected. The situation was becoming a serious one. The sanitary inspector, hearing of a contemplated prayer-meeting at a house where a death had taken place, resolved that at all hazards he would prevent this and to do so he remained at the house during the whole of the afternoon prior to the day of the funeral. Towards evening, when he thought the prayer-meeting had been abandoned, he left the house for half an hour. During that time a few friends assembled and the meeting was held. Such determined recklessness on the part of the people of the house and those attending the meeting will not be met by a casual reprimanding, though the inflicting of a penalty for obedience to religious feeling will be very odious. Yet matters have now become so serious that it may be necessary to engage special constables to assist the officers in their endeavours to save the lives of people. It seems curious that such measures should be required in the twentieth century to enforce elementary precautions against the spread of an infectious disease.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

The Rebuilding of the Royal Infirmary, Glasgow.

THE scheme for the rebuilding of the Royal Infirmary as a memorial of the Queen's Diamond Jubilee has advanced

a stage. At a recent meeting of the committee the report of the assessor on the plans sent in by the competitors was considered, and after a vote had been taken the plan submitted by Mr. James Millar, M.I.A., was adopted. It is perhaps noteworthy that the scheme selected by the committee is not the one placed first in order of merit by the assessor. The scheme adopted provides for the complete reconstruction of the infirmary. Provision will be made for nearly 700 beds and the arrangements in every respect are to be of the most modern type. The estimated cost is £224,500. Towards this sum nearly £100,000 have already been raised, and as the infirmary is the oldest medical charity in the city it is anticipated by some that a scheme which will make the institution one of the largest and most complete hospitals in the kingdom will be enthusiastically supported by the citizens. It is possible, however, that the new scheme for rebuilding may be submitted to some adverse criticism.

Meat Extracts.

Dr. Hugh Galt has presented to the Glasgow Philosophical Society a report on an examination of a number of well-known meat extracts all claiming more or less energetically to be concentrated foods. His verdict is entirely opposed to this claim, as his analyses show that not one of those examined contains more than a small proportion of nutritive matter. Their value, he concludes, is purely a stimulating one, depending entirely on the proportion of meat bases present.

The John Reid Prize.

This prize, which is intended to promote pathological research and is awarded for an investigation conducted in one of the medical schools of Glasgow, has been given for two years to Mr. John McIntyre of St. Mungo's College. Mr. John McIntyre's thesis was on Some Points in the Formation of the Connective Tissue of the Liver, with Special Reference to Hepatic Cirrhosis.

Medical Presentation.

Dr. A. Johnston, medical superintendent, and Miss Adams, matron of the Glasgow Fever Hospital, have received handsome Christmas presents from the nursing staff in appreciation of their efforts to secure the comfort of the nurses and other hospital workers.

Glasgow Corporation and Consumption.

A considerable number of years ago the Glasgow Medico-Chirurgical Society drew the attention of the corporation to the fact that tuberculosis is to be regarded as an infectious disease and urged the authorities to take the steps necessary to prevent the spread of the malady. The memorial in which these considerations were advanced was referred by the health committee to Dr. J. B. Russell, at that time medical officer of health to the city. Dr. Russell made a report on the whole question and this was published and widely circulated. The matter has not been allowed to rest. The corporation has now decided to confer with representatives of the Glasgow medical societies with a view to holding a meeting of the citizens for the purpose of educating public opinion on the necessity for providing in the interest of the public health sanatoria or hospitals for the isolation and treatment of consumptive patients. No doubt this determination has been aided by other influences, but the Glasgow Medico-Chirurgical Society may justly claim the credit of being one of the earliest educators of the public conscience as regards the infectious nature of pulmonary consumption. The original memorial drawn up by the society was signed, among others, by Sir William Gairdner and the late Professor Joseph Coats.

Aberdeen Hospital for Incurables.

At the annual meeting of the managers and subscribers held on Dec. 27th it was reported that on the ordinary income there was a deficit of a little more than £446, but owing to the receipt of legacies the deficiencies of the past and former years had been wiped out, and a favourable balance of £352 odd was left. The number of patients at the close of the year was stated to be 73.

Aberdeen Royal Infirmary.

The appeal issued in connexion with the annual Hospital Sunday collection to be made in the churches on Jan. 6th, 1901, states that between Jan. 1st and Dec. 22nd, 1900, the number of patients treated in the wards was 2596; the number who had received advice and medicine as out-patients was 3597; and the casualty cases (minor accidents) numbered 3534—total, 9727.

New Asylum near Aberdeen.

The Aberdeen City Parish Council have contracted with a local builder to execute the mason work of a new asylum at Kingseat, Newmachar, for the sum of about £30,000.

New Hospital in Banffshire.

Mr. James Campbell, Old Cullen, has intimated that he will be glad to give £3000 towards the cost of an isolation hospital for infectious diseases for Banff and the lower districts of Banffshire, including all the boroughs. The scheme has been favourably entertained by the various local authorities concerned.

Jan. 1st.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

Health of Belfast.

AT a meeting of the Belfast City Council on Jan. 1st reference was specially made to the fact that in 1900 there was the lowest death-rate on record in Belfast, 21·3 per 1000. For the period between Nov. 18th and Dec. 15th, 287 cases of zymotic disease were reported—viz., 90 of typhoid fever, 53 of scarlet fever, 72 of simple continued fever, 33 of erysipelas, 24 of diphtheria, 11 of membranous croup, and four of puerperal fever. 231 deaths occurred from phthisis and diseases of the respiratory organs. The number of cases of typhoid fever notified and the deaths therefrom are steadily decreasing. The epidemic of scarlet fever seems to be subsiding. The assistant surveyor has been instructed to furnish an estimate of the cost of erecting an arrangement for the destruction of condemned meat (mainly tuberculous) at the abattoir similar to that in use at the Central Meat Market, London. This is due to the exertions of Dr. H. O'Neill, at whose suggestion a deputation from the market committee of the Belfast Corporation visited various places for the purpose of acquiring knowledge as to meat inspection.

The Royal Victoria Hospital, Belfast.

Dr. W. Calwell (one of the physicians) has been appointed to organise and to take charge of the new department for diseases of the skin; and Dr. R. J. Johnstone and Dr. V. G. L. Fielden have been selected as the new anæsthetists. Dr. Henry O'Neill (on resignation of the post of surgeon to the Royal Victoria Hospital) presented a gift of £100, which is, in accordance with his wishes, being utilised in the purchase of instruments and appliances for the benefit of patients under treatment. Mr. T. S. Kirk has been appointed to take charge of the Throne Children's Hospital, an annexe of the Royal Victoria Hospital.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Cultivation of the Microbe of Soft Chancre.

AT a recent meeting of the Society of Biology M. Besançon, M. Griffon, and M. Le Sourd communicated to the society that they had succeeded in cultivating the microbe of soft chancre with great ease, although up to the present time its cultivation had been found very difficult. They used blood gelose as a culture medium, a substance which M. Besançon and M. Griffon had previously found singularly adapted for the growth of the bacilli of tubercle and of that of gonococcus and also of the coccus of meningitis. The three observers reported that some 24 hours after this culture medium has been inoculated with material from a soft chancre shining round colonies make their appearance which at the end of 48 hours become greyish and opaque. When taken up for microscopical examination they glide away before the platinum loop and when spread out on the slide are difficult to separate. They are seen to be formed of bacilli either isolated or grouped in a mass or sometimes in chains. Their morphology answers to that

which Ducrey, Unna, and Nicolle described as existing in microbes from the pus or sections of a chancre. In the liquid which collects at the bottom of the culture-tubes the microbe develops in a characteristic form—namely, as long slender chains. The organism preserves its vitality and virulence in the blood gelose for a long time. By using a colony taken from a culture of the eleventh generation the three observers were able to reproduce a typical soft chancre. Ducrey's bacillus was found to develop well in the liquid serum of a rabbit. This culture medium became turbid and full of little flocculent masses which under the microscope were seen to consist of bacilli growing in entangled chain forms. But their vitality in this medium was of short duration. M. Besançon and his coworkers consider that blood gelose is evidently the preferable culture medium for this organism, and think it possible that this method of examination may be useful for diagnostic purposes and do away with the necessity for having recourse to inoculation for proof of the nature of a chancre.

State Subvention for the Assistance Publique.

The Assistance Publique of Paris has to dispense very considerable sums of money and these are always increasing, although the receipts hardly increase at all. The Assistance has to provide hospital accommodation for a daily increasing number of patients—it provides alms, food, clothing, fire, and lodging for an ever-growing crowd of poor of a city the population of which is always being swelled by an influx from the country. As it is the municipal funds and the rates paid by Parisians which mainly make up the income of the Assistance it is obvious that Paris and the Parisians provide to a very large degree for the poor of the whole of France, and not merely for those of their own city. This is especially the case with the hospitals where innumerable patients from the country are treated, to say nothing of foreigners. These two classes have enormously increased of late owing to the Exhibition. Numbers of countrymen and foreigners who came to work there preferred to stay in Paris instead of going home, and a number of them, work having stopped, drift into vagabondage and swell the criminal classes. Those who remain honest are very hard put to it, and the funds of the Assistance have been very strained in providing for them. The Municipal Council in view of these facts has passed a number of resolutions, amongst others one to the effect that donations, &c., and work should be reserved by preference for those poor who have lived in Paris for a certain number of years. With regard to the hospitals, M. Gelez gave it as his opinion that Paris could not continue to be a central hospital for the whole of France without the help of the whole country, and that either the State or the Department should contribute. In the budget of the Assistance for 1901 the estimated receipts are 11,000,000 francs below the estimated expenses, and this deficit is in great part due to an expense of 3,500,000 francs incurred by Paris in providing for the provincial poor. The Municipal Council asks that the State should subsidise the Assistance Publique by a sum of 10,000,000 francs per annum.

Episodes of the Small-pox Epidemic.

A Paris medical practitioner has just formulated a complaint dealing with the following circumstances before the Syndicate of Medical Practitioners of the Seine. He was asked to vaccinate a member of a family whose medical attendant he had been for some years past. The patient was a young man who had that day to present himself before the Faculty of Medicine for registration and who had to be provided with a certificate of revaccination. Armed with the certificate of his medical man he repaired to the office of the Faculty and was there told that the certificate was of no use, but that he must go and be again vaccinated at one of the two re-vaccination stations appointed by the Faculty, which he accordingly did, although still bearing on his arms the marks of the vaccination performed that very morning. The council of the syndicate could only say that such proceedings were very annoying for the average general practitioner and many members of the syndicate were anxious to apply to the Faculty of Medicine to have these restrictions removed; but the president of the syndicate reminded the meeting that the Faculty was not responsible for the regulation, which was due to a decree of the Minister of Instruction bearing date Jan. 6th, 1891. Then was the time when protests should have been made. Another interesting case from the point of view of public health arose during the epidemic. The porter of a block of flats was attacked by small-pox. One of the tenants, who happened to be a lawyer, pressed the landlord to have the porter removed to the hospital and to have his rooms disinfected, for, as he said, every tenant passed the lodge every day and so ran great risk of infection. The landlord refused and so the lawyer haled him before the court to recover damages for the dangers to which he and other tenants had been exposed. But before the case came on the landlord gave in, and had the porter removed and his rooms disinfected. This was a regrettable result from one point of view, for the judgment of the court would have been of great interest to sanitarians.

The Sanatorium of Angicourt.

The sanatorium at Angicourt intended for the treatment of tuberculous patients is on the point of being opened. It has taken 14 years to build. I shall in my next letter lay before your readers some details of the working of the institution.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Prolongation of the Medical Curriculum.

IT is announced that various alterations are to be made in the conditions under which medical qualifications are granted, and a Bill on the subject has been submitted by the Imperial Government to the Federal Council. The existing law, which states that a candidate becomes qualified on passing the State examination, is to be altered as follows: Candidates are to become qualified when they have passed the State examination and spent a year in practical work. A qualification may be refused to candidates who have committed grave criminal or ethical misdemeanours. The Bill provides that the time of study will be five years instead of the present term of four and a half years. After having passed the State examination the candidates have to apply themselves to practical work under the direction of competent physicians and surgeons (probably in hospitals only, though nothing has yet been decided). The fees for the preliminary examination will be raised from 36 marks (£1 16*s.*) to 90 marks (£4 10*s.*), and the fees for the State examination will be 200 marks (£10). The study of medicine, which has hitherto been restricted to the pupils of the "Gymnasia," will now be thrown open to the pupils of the "Realgymnasia" and the "Oberrealschulen." Only abstracts of the Bill have as yet been made public. I will return to the subject when more particulars are known. The prolongation of the curriculum, which hitherto has occupied four and a half years and in future will occupy six years, including the practical year, will make the study of medicine rather expensive, but it is very doubtful whether the present rush to a medical career will be checked by the additional expense, because the area from which students are drawn will be enlarged by the admission of the new class of pupils coming from the "Realgymnasia."

Statistics of the Medical Profession.

Dr. Schwalbe's Medical Directory for 1901 has just appeared. The statistics in this valuable book show that the number of medical men in Germany has again increased, being now 27,374, or 2·6 per cent. more than in the previous year. In 1899 the increase was 3·6 per cent.; between 1894 and 1898 it was from 3·6 to 3·9 per cent, In Prussia there are 16,498 medical men, in Bavaria 3036, in Saxony 2048, in Würtemberg 881, in Baden 1087, in Hesse 683, in Alsace-Lorraine 683, and the remainder in the other States of the Empire. In 1900 there were 5·24 medical men for each 10,000 inhabitants, the proportion being 5·11 in 1899. On an average 5·06 medical men resided in an area of 100 square kilometres (38 square miles) in 1900 and 4·94 in 1899, but this number varied very much in the different parts and provinces of Germany. In Saxony, for instance, there were 13·66 medical men on the above area; in Prussia, 4·73; and in Bavaria, 4·00. In several districts of Prussia the proportion was exceedingly small, being only 0 99 in the district of Cöslin and 1·11 in the district of Gumbinnen. Also in some districts of Bavaria there were only 1·68 medical men on 100 square kilometres. As to the great towns, Berlin has 2360 medical men, as compared with 2314 in the previous

year, being one medical man for each 798 inhabitants; Munich has 694 medical men, Hamburg 585, Breslau 545, Dresden 428, Leipsic 416, Cologne 338, Frankfort 334, and Strassburg 213. The above statistics have been published by Dr. Heiman in the *Deutsche Medicinische Wochenschrift*.

Local Taxation of the Medical Profession.

By a recent law every medical man is required to pay a certain sum to the medical chamber of his district, and the money thus collected is to be used for the expenses of the chamber and for a fund to support distressed medical men of the district or their families. It is left to each chamber to fix the amount to be paid in this way and to decide whether it shall be uniform for all or regulated according to the income of individual practitioners. This question was discussed at a recent meeting of the medical chamber of Berlin and the province of Brandenburg. The committee proposed that a uniform rate of 10 marks (10*s*.) should be paid by every practitioner of the district and that an additional sum should be charged to those earning more than 3000 marks (£150). After a long and animated debate the chamber adopted these proposals. As to the fund for the support of distressed members the chamber was of opinion that a scheme of regulations should be prepared by a special committee and afterwards submitted for the consideration of the chamber.

ROME.

(FROM OUR OWN CORRESPONDENT.)

The Medicinal Prophylaxis of Malaria.

IT has been abundantly demonstrated that protection against the bites of mosquitoes is an effectual measure in the prophylaxis of malaria. It has also been proved that much may be done to limit the extension of the disease, at any rate in suitable localities, by destroying the mosquitoes themselves both in their larval and adult states. But the difficulties encountered in carrying out such measures in practice efficiently and on a large scale have led several investigators to attempt what is undoubtedly the ideal method of prophylaxis—namely, the immunisation of the human organism against the infection. Various agents have been used more or less successfully with this object, but none with more encouraging results than the medicinal substance euchinin employed by Professor Celli. This is an almost tasteless crystalline derivative of quinine obtained by acting upon the latter with ethyl-chlorocarbonate. It is prepared in tabloids by Zimmer of Frankfort, and is given in doses of half a gramme (seven and a half grains) per diem for adults and a quarter of a gramme for children twice daily before food. Its administration in this way, even when continued for months, does not appear to give rise to any ill-effects and can therefore be begun at the commencement of the malarial season in June and kept up regularly without inconvenience until its termination at the end of November. For these reasons it was selected by Mori[1] for a series of experiments which he has carried out under Professor Celli's supervision during the past season in the Roman Campagna at three places, all with a highly malarial reputation. The subjects of the experiments were selected from six families of peasants and numbered 42 individuals, 16 of whom resided at Amatello, 14 at the Affitti del Gotti, and 12 at the Caldanelle and Lavoriera Bacci. In each of these localities there were other persons who served as controls. Of the first group of 16 subjected to the euchinin treatment 6·25 per cent. sickened, while of the controls 81 per cent. took fever. Of the second group of 14 the percentage affected was 28·57, whilst among the unprotected it was 85·76. (This locality is at all times extremely unhealthy.) Of the third group, numbering 12, none contracted malaria, whereas among the controls 75 per cent. were affected. The total results were therefore as follow. Of 42 persons living in malarious surroundings subjected to the preventive treatment by euchinin only five, or 11·9 per cent., became infected, while of 47 persons not so protected but living otherwise under the same conditions 39, or 82 97 per cent., were attacked. It should be added that in those who took the infection, notwithstanding the use of the euchinin, the disease showed itself in a very mild form easily cut short, except in one case of quartan fever, by ordinary treatment, whereas in those not immunised the infection took severe intractable forms with a tendency to successive relapses.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

A Novel Application of Vaseline in Surgery.

A VERY interesting application of vaseline for surgical purposes has been made by a well-known Vienna surgeon, Dr. R. Gersuny. Without previous experiments on animals Dr. Gersuny made a trial of vaseline injected under the skin or mucous membrane as a substitute for some of the artificial contrivances of the surgical instrument maker. His first case of importance treated in this way was operated on a year ago. The patient was a girl, 18 years of age, on whom a successful operation for cleft palate had been performed, but her voice remained nasal as before the operation; by injecting vaseline under the mucous membrane of the velum palati and uvula an artificial obturator was produced the effect of which was that her speech became normal and even difficult consonants like "g" could easily be pronounced. In this case the submucous injection of the vaseline caused considerable pain for the first two days, perhaps on account of the pressure exerted by it on the sensitive bones of the palate, but the pain soon subsided. The injection has remained in position till now—namely, for a period of more than a year—without any disagreeable consequence, and the compact mass formed by the vaseline has not undergone any change in its size or shape during the whole time. In some other cases where this method was tried no pain resulted from the injection of the vaseline. An injection of cocaine is generally given before the injection of the vaseline. The effect produced by the vaseline—namely, the filling out of a cavity or the formation of an artificial protuberance—remains unaltered for many months. Dr. Gersuny has operated in this way on an Indian lady from Bombay suffering from congenital depression of the nose, for which a plastic operation was not considered advisable by the various surgeons who had been previously consulted. A very important use of this method has been made by Dr. Gersuny in the treatment of incontinence of urine, and a successful case of this kind was shown lately at a meeting of the Vienna Obstetrico-Gynæcological Society. The patient was a woman, aged 25 years, who suffered from vesico-vaginal fistula, the result of parturition. The fistula had been operated on, but the sphincter vesicæ remained inefficient. With a view to the remedying of this latter condition torsion of the urethra had been performed by a surgeon, and as the state of the patient did not improve she had been operated on by Dr. Gersuny himself six times since 1896, but on account of ulcerative processes these operations (torsion of the urethra) did not produce any lasting benefit. In July, 1900, the patient came again under the treatment of Dr. Gersuny with almost complete incontinence of urine. As the urethra had been so much lacerated by the previous operations Dr. Gersuny tried to produce closure of the vesical orifice by an artificial annular mass formed by injections of small quantities of vaseline into the prolapsed folds of the mucous membrane of the bladder. The injections were made through the mucous membrane of the vestibulum and through the vagina in the neighbourhood of the vesical orifice. The total quantity of vaseline injected was 3·3 cubic centimetres. After the operation the incontinence ceased, but in a few days it commenced again when the patient was walking or sitting. A second injection of vaseline was therefore made by which the deposit formed around the vesical orifice was so much thickened that a firm ring projecting into the vagina resulted. After the second injection she was able to retain her urine for some hours: she then complained of tenesmus for three days (she was also suffering from gonorrhœa). But on the fifth day after the second injection of vaseline she had regained control of her urine so that when walking she remained dry for one and a half hours. Four weeks later she could retain her urine for five hours even when walking. The vaseline deposit, which was about as large as a cherry, remained of the same size during the whole period. At the

present time, five months after the operation, the state of the patient has not changed; she can hold her urine for five or six hours when in the erect posture and from 10 to 12 hours when recumbent, and the capacity of her bladder now amounts to 350 cubic centimetres (12 fluid ounces). Dr. Gersuny employs for his injections the unguentum paraffini of the Austrian Pharmacopœia, melting at 40°C. The vaseline is first sterilised by boiling and is injected in a semi-liquid state. It does not produce any inflammation, but it seems that slight proliferation of the connective tissue takes place round it so that the vaseline becomes encysted. The histological changes produced by the injections are now being studied at Dr. Gersuny's laboratory, and experiments on animals are being made for the same purpose. The course of the cases treated up to the present proves that the vaseline remains unaltered in the place where it was deposited, that it does not become absorbed, and that it is without action on the tissues of the body. The size and shape of the vaseline deposit have not changed since the date of the operations, though some of them were performed more than a year ago. The changes in the connective tissue around the injected vaseline seem to be caused by mechanical pressure, and they are somewhat analogous to the very marked effects produced by the chemical action of Professor Lannelongue's injections of chloride of zinc. It is obvious that this method may find a very wide use in surgery, especially for elevating and supporting the skin over unsightly depressions, for the formation of artificial obturators, and for the treatment of various prolapses, as for instance of the rectum. The effect of a pessary might also be produced by circularly arranged injections of vaseline under the mucous membrane of the vagina, as has been shown recently by a case of vaginal prolapsus successfully treated in this way at the gynæcological clinic by Dr. Halban. At Dr. Gersuny's hospital experiments are now being made on the prevention of ankylosis after resections of joints by interposing vaseline partitions between the ends of the resected bones.

CANADA.

(FROM OUR OWN CORRESPONDENT.)

Canadian Beer.

THE alarming news from Manchester in reference to the deaths and wide-spread illness through beer-drinking has caused some little concern to the lovers of that beverage in Canada, and inquiries have been numerous as to whether the same misfortune might not occur here as has occurred in Manchester and its vicinity. The vice-president of the Canadian Breweries (Limited) has, however, given out a statement to the press which will no doubt quiet any alarm that may have been engendered by reports from the mother country. Canada has never adopted the "free mash-tun" principle, and the law here provides that no substitute whatever for malt shall be used, as the duty is levied directly on the malt and no further duties are imposed on the beer produced. In Canada all beer is manufactured exclusively from malt and hops and no substitutes are permitted for these substances under heavy penalties. It is a well-known fact that Canada produces the finest barley grown on this continent and therefore the drinkers of Canadian beers have two substantial guarantees of purity which are said to be absent in England and the United States, the two great countries which have adopted the "free mash-tun" principle—(1) that no substitute for malt is permitted, and (2) that owing to the high duty on malt only that made from the choicest barley may be employed with economy.

New Civic Hospital for Montreal.

Last week representatives from all of the hospitals in Montreal, both French and English, met the city council and perfected plans for the immediate erection of a new hospital for contagious diseases, as the present one is a very antiquated structure. Four pavilions for hospital purposes will be erected with a central administration building. Each pavilion will be of two floors containing the necessary accommodation for about 50 beds, with 12 beds for private cases. There will be provision made for all cases of diphtheria, scarlet fever, small-pox, measles, typhoid fever, and other infectious diseases liable to break out at any time in the city. The administration building will contain the medical officers' apartments, observation-rooms, &c. A fine block of land has already been secured. The control of the institution will be vested in a joint board of nine members, five of whom, including the chairman, will be appointed by the city council, and two by the executives of the English hospitals, while two will come from the French hospitals. All matters of finance and expenditure by this board will be subject to ratification by the city council. The estimated cost will be $100,000, which will be raised by a special loan.

Manual Training Schools.

Through the generosity of Sir William Macdonald of Montreal manual training schools will, after Jan. 1st, 1901, be a part of the public school system in every province in this Dominion. These schools will be established in the following places: Charlottetown and Summerside, Prince Edward's Island; Truro, Nova Scotia; Fredericton, New Brunswick; Waterloo, Knowlton, Bedford, Montreal, and Westmount, Quebec; Ottawa and Brookville, Ontario; Winnipeg, Manitoba; Regina and Calgary, North-west Territory; and Victoria and Vancouver, British Columbia. Arrangements have been made for five instructors in Winnipeg alone, where 1000 boys will take the course. These classes will be made up from the three highest forms in the public schools in the places named; and the teachers, in all about 30, have come, or are coming, from England and the United States under three-year engagements. On Jan. 1st 5000 boys will be taking this course. Sir William Macdonald provides all the equipment of every school and pays the salaries of all the teachers and the cost of maintenance for the three years.

The Smoke Nuisance in Toronto and Montreal.

Toronto has just completed a costly new city hall, and as it is becoming discoloured by the smoke of a large industrial establishment in its immediate neighbourhood the city council has taken up the question of compelling all manufacturers to consume their own smoke. Some 20 years ago Professor Carpenter, the eminent physiologist, visited Toronto and was then very much surprised that a city of such beauty and such salubrity of climate should be befouled, and have the health of its citizens jeopardised, by the ever-pouring out of these clouds of black smoke from the tall chimneys of the great manufactories of the city. Montreal suffers greatly from the same nuisance, and it is understood that the city fathers of that metropolis are to follow the lead of Toronto in maintaining a purer atmosphere for its citizens. Cape Breton is a part of Canada which is now passing through a period of great development through the energy of the well-known Boston capitalist, Mr. Henry M. Whitney. This gentleman believes that the best way of dealing with this smoke nuisance in a satisfactory manner is to provide smokeless fuel, which he is now doing on a large scale for the city of Boston. He has erected 400 by-product coke ovens in which the coal of Cape Breton is converted into a cheap smokeless fuel. He states that the gas, tar, and ammonia which are saved more than pay for the trouble of converting the coal into coke. When this fact becomes to be generally recognised in Canada its cities and towns will produce a purer atmosphere for their inhabitants.

Free Consumption Sanitarium for Toronto.

The National Sanitarium Association which controls the Muskoka Cottage Sanitarium at Gravenhurst has offered to construct, equip, and maintain an institution for the consumptive poor of Toronto, without asking any municipal aid from the city on capital account, with the exception of the ordinary per diem hospital allowance of 40 cents for each patient. The erection of the building will be begun at once and it will be ready in a year for the accommodation at first of 50 patients. This accommodation will be for those patients who are in the very first stages of consumption, and the association proposes to erect the institution in the immediate neighbourhood of the Muskoka establishment. Arrangements have already been made with the Grand Trunk Railway Company for free transportation of 100 patients per annum to and from Gravenhurst, with half rates for all over 100. The advantages for its location in Muskoka are the climate, the site, and the suitability as already demonstrated by the results achieved at the Muskoka Cottage Sanitarium. When this part of the work is under way the association will then take up the question of providing accommodation for advanced cases at

a distance from the city of not more than five or six miles. Toronto was about to submit a by-law to the ratepayers for funds to the amount of $50,000 towards this purpose, but the offer of the National Sanitarium Association will now render this unnecessary.

Providing for the Insane in Ontario.

The Government of the Province of Ontario has lately been coming in for some severe criticism at the hands of the medical and lay press for its failure to provide ample and proper accommodation for the insane of the province. Nearly 100 of these unfortunate people can be found in the common gaols, and it is said that in Toronto alone some 49 lunatics are confined who are awaiting transference to the asylums. These, however, are all full, so the lunatics must continue to be housed with thieves and other criminals. Work is being pushed on at the old Victoria College at Coburg, which, when completed, will accommodate 200 patients, and a new boys' reformatory is about to be erected in Oxford county, when the present reformatory at Penetang will be available for further accommodation for the insane. With this added increase to their accommodation the Government will hereafter endeavour to keep abreast of the growing requirements of this unfortunate class of the community.

A Toronto Physicians' Protective Association.

In its November issue the *Dominion Medical Monthly* advocates the formation of the above association. It states that in Detroit an organisation of this character has been formed and that over 400 of the physicians of that city have signed the roll of membership and that the organisation is proving a great benefit to the profession in that city. Other cities of the United States are said to be following in the footsteps of Detroit; in fact, organisation amongst medical men is in the air across the border. It appears that there has been some quiet talk going on among the members of the medical profession in Toronto tending to the formation of some sort of protective association, though on what lines is not apparent. There is, no doubt, wide room for such an organisation, and it is altogether probable that the near future will see something tangible done in the way of lightening the burdens under which the profession suffers in this city. Toronto is a rather conservative city—an attribute which has to a great extent been incorporated in the medical body—but when professional organisation has proved to be successful in neighbouring cities the benefits to be derived therefrom cannot long be resisted.

Toronto, Dec. 17th, 1900.

NEW YORK.

(FROM OUR OWN CORRESPONDENT.)

Typhoid Fever prevented by a Filtering Plant.

THE city of Albany formerly had an evil reputation because of the prevalence of typhoid fever. It obtained most of the water it used from the Hudson river, which was contaminated by sewage from all the towns and cities along the Mohawk and the Hudson rivers and their tributaries, some of which penetrate into Massachusetts and the border factory towns in the Berkshires. Strangers visiting Albany, many of them members of the Legislature or students attending the schools, sickened and died. No family in Albany of any prudence drank water from the Hudson river unless it had been first boiled and put through a good filter. Thousands of persons never drank any of the water provided by the city but bought spring water which was peddled through the streets. Nevertheless, there were a large number of fatal cases of typhoid fever in the city and Albany suffered in reputation. In 1896 the Board of Water Commissioners changed the intake of water for the city, which drew from the Hudson river opposite the heart of the city and below some of its sewers, two miles further up the river, to a point above all the local sources of pollution, and pumped the water by low-lift pumps to a settling basin, from which it could flow to sand filters and be purified. The water after being filtered is pumped to reservoirs on the hills west of Albany and thence is distributed through the city. A small part of the city is, however, still supplied with the unfiltered water. The report of the first year's results is as follows. The bacterial removal has averaged 99 per cent. For nine months of this year there have been reported to the Board of Health 30 deaths from typhoid fever. Of these, 12 deaths were alien cases—i.e., the attending physician has reported that the patient contracted the disease outside of the city—four cases were "unaccounted for" and occurred in institutions where it was impossible to obtain information concerning them, or else they lived within the city limits, but in localities where they did not have a city water-supply. Of the remaining 14 cases one occurred in the part of the city supplied with unfiltered water, five occurred in the portion of the city supplied with mixed filtered and stream water, and eight occurred in the section of the city supplied with only filtered water. This number of deaths reported, 30, compares favourably with 83 deaths reported for the same months in the year before the filter was put in operation. The average number of deaths for the nine years previously to the construction of the filter plant was 67, so that more than 50 per cent. decrease in the deaths from this disease has followed on the new works.

Bureau of Animal Industry.

This bureau of the United States Government reports that during the year the number of abattoirs and packing-houses receiving the benefit of inspection was 148 in 45 localities, as against 138 in 41 localities in the preceding year. The total ante-mortem inspections of cattle aggregated 53,087,994; the animals rejected, subject to post mortem, were, at abattoirs 5958, and in stock-yards 153,561. The total post-mortem inspections were 34,737,613 and the total carcasses condemned were 61,906. In the microscopic inspection of pork 999,554 carcasses were examined. Of these but 19,448, or 1·95 per cent., were found to contain living trichinæ. The work of preparing serum for treating hog cholera and swine plague and experiments in treatment therewith are continued, with results which, while they do not justify definite conclusions as yet, are sufficiently encouraging to justify continued experiments, including some on entirely new lines. With regard to rabies, the secretary declares that this disease is unfortunately on the increase in the United States and that local authorities in most cases have not efficiently controlled its outbreaks. He also earnestly recommends an inspection of dairy products designed for export. Elaborate work in the investigation of food adulteration has been continued.

Proposed Change in the Management of New York City Hospitals.

The Charter Revision Commission has proposed an amendment which provides that on Feb. 1st, 1902, Bellevue, Gouverneur, Harlem, and Fordham Hospitals, and the Emergency Hospital for Women, shall be taken from the Department of Public Charities and be vested in a board of trustees appointed by the mayor. The city hospitals would, therefore, be brought under the same system of control that prevails in private hospitals.

Massachusetts State Sanatorium for Tuberculosis.

From the fourth annual report of this institution, the first established in this country, the following facts appear. 132 patients remained from one to 19¾ months. In 82 incipient cases 53 patients were dismissed as apparently cured, 28 were improved, and one was not improved; none died. Of moderately advanced cases (40 in all) six patients were dismissed as cured or the disease arrested, 18 were improved, 15 were not improved, and one died. Of the patients in 10 far advanced cases three improved, six did not improve, and one died. The total was 132; of these 59 were apparently cured or the disease was arrested, 49 were improved, 22 were not improved, and two died. Dr. Bowditch, the visiting physician, says, "The chief value of such an institution as this sanatorium is its educational influence upon the community at large. Abundant and gratifying proofs of this are constantly being shown to us by the numerous letters received from former patients, telling us of their improved methods of life and their endeavour to teach their relatives and friends the importance or fresh air, good food, and regular living as the best method for the prevention of disease. The sanatorium is, therefore, in one sense a great educational establishment, and as such should receive the hearty and generous support of everyone who is desirous of combating the ravages of tuberculosis."

Separate Prisons for Tuberculous Convicts.

Dr. W. H. Blake, physician to the board of inspectors of convicts for Alabama, states that the statistics of deaths among the convicts in the Alabama State prisons for the

past 20 years show that for the first half of this period tuberculosis caused 20·3 per cent. of the total mortality; for the latter half it caused 42 per cent. In the penitentiaries of the different States, of the total deaths, the percentage caused by tuberculosis reads thus:—Mississippi, 20 per cent.; Arkansas, 20 per cent.; Florida, 30 per cent.; Ohio, 31 per cent.; Michigan, 33 per cent.; Alleghany County Workhouse, Pa., 33⅓ per cent.; Virginia, 41 per cent.; Kentucky, 42 per cent.; Joliet, Ill., 70 per cent.; Huntsville Penitentiary, Texas, 33 per cent.; Washington, 16 per cent.; Connecticut (1898), 60 per cent.; and in 1897 every death that occurred in this penitentiary was caused by tuberculosis. In the Alabama convict institutions the inmates are not kept in separate cells, but from 50 to 100 are confined together in one large cell. Tuberculous convicts, unless in an advanced stage of the disease, are shut in with the healthy inmates; the consequence is that the prison is to a large extent a death-trap and the mortality from phthisis is increasing. Dr. Blake urges a separate camp for the tuberculous convicts, the further from the other prisons the better, in order to give the non-tuberculous prisoners the greatest possible immunity from the disease. This would give the tuberculous man better treatment and the healthy man a chance to remain well. In this matter the duty of the State is plain—it has the right to deprive the offender of his liberty but it has not the right to deprive him of his health.

Dec. 19th, 1900.

Obituary.

THOMAS TAYLOR, M.R.C.S. ENG., L.S.A.

ON Dec. 23rd there passed away one of the best-known practitioners of East Essex and one of the few now left who have served under the old apprenticeship system. Born in 1819, Thomas Taylor when 15 years of age was apprenticed for five years to Mr. Hester, a prominent surgeon at Abingdon. On the termination of his articles he came to London and entered at St. Bartholomew's Hospital, living whilst there in the house of Mr. Stone, the then medical officer to Christ's Hospital. Here Taylor's love of nature asserted itself, for he did his best to cultivate a window garden. Qualifying M.R.C.S. Eng. in 1842 and L.S.A. in 1843, he shortly afterwards obtained the appointment of house surgeon at the Essex and Colchester Hospital, where he remained till 1853, when, being desirous of settling down, he purchased a practice in the village of Bocking, where he remained for the rest of his life.

Thomas Taylor possessed a strong and attractive personality and was a familiar figure in the district where he lived. He delighted in seizing opportunities for quietly and unostentatiously giving pleasure to others and he was a strong supporter of the Royal Medical Benevolent College, having acted as local secretary for some years. His professional services were highly appreciated, his practice extended over a wide district, his opinion was frequently sought in consultation by his colleagues, and he always kept himself well abreast with the advance of medical knowledge. To his patients he was the same to all alike, gentle and sympathetic; and as he knew the personal history of a large proportion of them and was gifted with sound judgment his advice was often asked on other than professional matters. Taylor's mind was essentially a scientific one; his interests outside his profession were in horticulture, geology, natural history, and microscopy, but particularly the first-named, for his acquaintance with gardening matters and with those interested in the same pursuit was extensive, and there are many gardens scattered over the country containing flowering plants the original stock of which was contributed by him. A few years back he found that he was suffering from glycosuria, on Dec. 20th lung symptoms showed themselves, on the 22nd coma set in, and the end came early and peacefully on the 23rd. The last rites were held on Dec. 27th, when a congregation which filled the parish church of Bocking assembled to express the esteem with which he had been regarded. Mr. Taylor was twice married and leaves behind him a widow, two sons, both in the medical profession, and two daughters, who have each married a medical man.

Medical News.

INFECTIOUS DISEASES IN LEICESTER.—The Sanitary Committee of the Leicester Town Council report that during the past 12 months the following certificates have been received. Diphtheria, 1415; scarlet fever, 797; erysipelas, 215; typhoid fever, 113; puerperal fever, 14; total, 2554.

THE Ipswich *Evening Star* of Dec. 29th, under the heading of "A Testimony to Antitoxin," gives a brief account of a testimonial recently presented to Mr. E. A. Hunt of Colchester in appreciation of his services during an epidemic of diphtheria which lately prevailed in the village of Old Heath. The testimonial was signed by 140 persons and was accompanied by a silver matchbox and a sovereign-case purchased by subscriptions limited to 6*d*.

THE LATE DR. A. LOWE.—Dr. Alexander Lowe died at his residence, Bailey-street, Brynmawr, Breconshire, on Dec. 26th. The deceased, who received his medical education at the University of Glasgow, graduated as M.B. and C.M. in 1882, and shortly afterwards commenced practice in Brynmawr, He was medical officer of health of the Llanelly Rural District Council and district medical officer of the parish of Llanelly. He was also surgeon to the collieries and a certifying factory surgeon for the district. Dr. Lowe, who had been for 18 years in practice at Brynmawr, was very highly esteemed in the town and neighbourhood and much regret is felt there at his early death.

FATAL DENTAL CASE.—An inquest was held at Newport (Mon.) on Dec. 28th and 31st, 1900, upon the body of a collier, aged 21 years, who had died on Dec. 27th at the dental surgery of Mr. H. W. Griffiths, L.D.S. R.C.S. Irel., of Newport, after having had 11 teeth extracted under nitrous oxide gas and ether. According to the report which appeared in the *Western Mail* Mr. Griffiths in his evidence stated that shortly after the operation had been successfully performed the deceased sprang up in the chair and gasped. Mr. Griffiths felt for an obstruction in the throat, but could find none. He applied artificial respiration and a medical man was fetched. A post-mortem examination showed that one of the sponges which had been used was fixed in the windpipe. Mr. Griffiths's female attendant stated that she believed she had taken out all the sponges from the patient's mouth. The jury returned a verdict that death was due to misadventure and that everything possible had been done for the deceased.

IMPORTANT SHIPPING CASE.—On Dec. 28th, at the Gravesend police-court, Henry Parry, the master of the steamship *Montery*, was summoned by the corporation of London, as the port sanitary authority, for an infringement of the by-laws made under the Public Health (London) Act, 1891, in failing to report to the medical officer of health on his arrival at Gravesend a case of dangerous infectious disease—viz., typhoid or enteric fever. Mr. Lewis Noad represented the owners, Messrs. Elder, Dempster, and Co., of Liverpool, and Mr. T. Vickery, the assistant City solicitor, appeared to prosecute on behalf of the corporation. Mr. Vickery, in opening the case, stated that the vessel arrived at Gravesend on Dec. 7th and was visited by the medical officer of health in conjunction with Her Majesty's Customs. In reply to the usual question as to whether all were well on board the master stated "All well" and subsequently signed a declaration to this effect, and further, that there had been no case of sickness during the voyage. On the following day it was found that the fourth engineer had been taken ill with typhoid fever on Nov. 14th and had been under treatment by the surgeon of the vessel since that date with the full knowledge of the master, who had entered the fact in his official log and had also reported it at Havre. The medical officer of health thereupon removed the patient to hospital and disinfected the vessel. These facts were not disputed by the defence and Mr. Noad on behalf of the master pleaded guilty and stated the circumstances under which the offence was committed. The bench imposed a penalty of 40*s*. with costs.

Appointments.

Successful applicants for Vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward it to THE LANCET Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, for publication in the next number.

BARRACLOUCH, H., M.B., C.M. Aberd., has been appointed Assistant Medical Officer to the Lunatic Asylum at Porirua, New Zealand.

BELGRAVE, T. R., M.E. Edin., M.R.C.S., has been appointed Officer of Health to the Abbotts Local Board of Health, West Australia.

BELL, H. T. S., L.R.C.P. Lond., M.R.C.S., has been appointed Acting Visiting Medical Officer, Jubilee Sanatorium for Consumption, Dalby, Queensland.

BLACK, GEO., M.B., M.S. Glasg., has been appointed Medical Officer to the Mokikinui Coal Mines, near Westport, New Zealand.

BLAXLAND, H., L.R.C.P. Lond., M.R.C.S., has been appointed Medical Superintendent, Hospital for the Insane, Gladesville, New South Wales.

BONNIN, J. A., M.B., B.S. Adel., has been appointed a Public Vaccinator for South Australia.

COOKE, T. A. B., L.R.C.P. Lond., M.R.C.S., has been appointed Medical Officer of Health, Neyland Urban District.

CORLIS, J., M.D., Ch.M. McGill Coll., Montr., has been appointed a Public Vaccinator for the District of Menzies, West Australia.

DUNCAN, WILLIAM, L.R.C.P., M.R.C.S. Edin., has been appointed District Medical Officer, Dover Union, vice J. Gordon, resigned.

ELVINS, R. S., L.R.C.P., L.R.C.S. Edin., L.F.P.S. Glasg., has been appointed District Medical Officer, Easingwold Union, vice W. C. Ellis, resigned.

GARDNER, T. FRED., M.R C.P. Lond., has been appointed Physician to the Royal Boscombe and West Hants Hospital.

GODSON, EDWIN, M.R.C.S., has been appointed Medical Superintendent, Hospital for the Insane, Kenmore, New South Wales.

LAVERY, E. A., L.R.C.P., L.R.C.S. Edin., L.F.P.S. Glasg., has been appointed Resident Medical Officer, Newcastle Hospital, New South Wales.

LEMIN, OSCAR, L.S.A. Lond., has been appointed Resident Medical Officer to the St. Marylebone General Dispensary, 77, Welbeck-street, Cavendish-square, W.

MUDGE, JAMES, L.R.C P., L.M. Edin., M.R.C.S., has been appointed Medical Officer of Health, Ludgvan Urban Sanitary District, vice J. Q. Couch, resigned.

MULLEN, W. L., M.D., Ch.B. Melb., has been appointed *pro tem.* Medical Superintendent to the Sunbury Lunatic Asylum, Victoria, Australia.

MURRAY, BABINGTON STEUART, M.B., C.M. Edin., has been appointed District Medical Officer for Bovey Tracey and Ilsington (North Devon).

POOLER, J. R., L.S.A. Lond., has been appointed House Surgeon to the Birmingham and Midland Ear and Throat Hospital.

RIDDELL, JAMES, M.B, B.S. Melb., has been appointed Honorary Medical Officer at the Port Augusta Hospital, South Australia.

RIGBY, HUGH MALLINSON, M.B., B.S. Lond., F.R.C.S. Eng., has been appointed Demonstrator of Anatomy at the London Hospital Medical College.

ROSS, CHISHOLM, M.D. Syd., Ch.M. Edin., has been appointed Medical Superintendent for the Insane, Callan-park, New South Wales.

ROW, L. E., M.D. Brux., L.R.C.P., L.R.C.S. Edin., L.F.P.S. Glasg., has been appointed Acting Health Officer at Townsville, Queensland.

RUTHERFORD, A. H., M.B., M.S. Edin., has been appointed Government Medical Officer at Casino, New South Wales, and also Medical Attendant upon the Aborigines at Casino.

WEBSTER, W., M.B., E.S. Glag., has been appointed Assistant Medical Officer to the Lunatic Asylum at Auckland, New Zealand.

WILLIAMSON, W. C., M.D., Ch.M. Irel., has been appointed Medical Superintendent, Hospital for the Insane, Parramatta, New South Wales.

Vacancies.

For further information regarding each vacancy reference should be made to the advertisement (see Index).

ADELAIDE HOSPITAL, South Australia.—Two Resident Medical Officers for twelve months. Salary £120 per annum, with board, &c. Apply to the Agent-General for South Australia, 1, Crosby-square, Bishopsgate-street Within, London, E.C.

BIRMINGHAM AND MIDLAND EYE HOSPITAL, Church-street, Birmingham.—Assistant House Surgeon. Salary £60 per annum, with apartments and board.

BOROUGH ASYLUM, Portsmouth.—Junior Assistant Medical Officer. Salary £120 per annum, rising by three equal annual increments to £150, with board, lodging, and washing.

BOROUGH OF RICHMOND (SURREY) AND THE HESTON AND ISLEWORTH URBAN DISTRICT JOINT ISOLATION HOSPITAL COMMITTEE.—Resident Medical Officer at the Isolation Hospital for Infectious Diseases other than Small-pox situate at Mogden, near Kneller Hall, Twickenham, unmarried. Salary £200 per annum, payable quarterly, with furnished house, coals, gas, and washing. Applications to the Clerk to the Committee, Hounslow, Middlesex.

BRIDGNORTH AND SOUTH SHROPSHIRE INFIRMARY.—House Surgeon. Salary £80, with board and lodgings in the infirmary.

COUNTY ASYLUM, Gloucester.—Junior Assistant Medical Officer, unmarried. Salary £120 per annum, rising £10 yearly to £150, with board (no stimulants), lodging, and washing.

EAST LONDON HOSPITAL FOR CHILDREN AND DISPENSARY FOR WOMEN, Glamis-road, Shadwell, E.—Pathologist and Registrar for one year.

EAST SUFFOLK AND IPSWICH HOSPITAL, Thorofare, Ipswich.—Two House Surgeons, unmarried. Salaries £100 for the senior and £70 for the second House Surgeon, with board, lodging, and washing.

EVELINA HOSPITAL FOR SICK CHILDREN, Southwark-bridge-road, London.—Senior Resident Medical Officer. Salary £70, with board and washing.

FISHERTON HOUSE ASYLUM, Salisbury.—Assistant Medical Officer, unmarried. Salary £150 per annum, with board, lodging, and washing.

GENERAL HOSPITAL, Nottingham.—House Physician for two years. Salary £100, rising £10 a year to £120, with board, lodging, and washing.

GREAT NORTHERN CENTRAL HOSPITAL, Holloway-road, London.—Senior House Surgeon for six months. Salary at the rate of £60 per annum, with board, lodging, and washing in the hospital. Also Junior House Physician for six months. Salary at the rate of £30 per annum, with board, lodging, and washing in the hospital.

GUEST HOSPITAL, Dudley.—Senior Resident Medical Officer. Salary £100 per annum, increasing by £10 a year to £120, conditionally, with board, residence, attendance, and washing.

HOSPITAL FOR WOMEN, Soho-square, London, W.—Assistant Physician.

HULL ROYAL INFIRMARY.—Senior House Surgeon for two years, unmarried. Salary 100 guineas per annum, with board and furnished apartments. Also Senior Assistant House Surgeon for not less than one year. Salary £40, with board and lodging.

KENT COUNTY ASYLUM, Barming Heath, Maidstone.—Fourth Assistant Medical Officer and Pathologist for two years, unmarried. Salary £175 per annum, rising £5 a year, with furnished quarters, attendance, coal, gas, garden produce, and washing.

LIVERPOOL DISPENSARIES.—Assistant Surgeon, unmarried. Salary £100, with board and apartments. Apply to the Secretary, Leith Offices, Liverpool.

LIVERPOOL STANLEY HOSPITAL.—Third Resident Junior House Surgeon. Salary £70, with board and washing.

LONDON THROAT HOSPITAL, 204, Great Portland-street, W.—Assistant Surgeon.

MILLER HOSPITAL and ROYAL KENT DISPENSARY, Greenwich-road, S.E.—Junior Resident Medical Officer for six months. Salary at the rate of £60 per annum, with board, attendance, and washing.

MONKWEARMOUTH AND SOUTHWICK HOSPITAL, Sunderland.—House Surgeon, unmarried. Salary £80 per annum, with board, residence, and washing.

NORTHAMPTON GENERAL INFIRMARY.—House Physician, unmarried. Salary £100 per annum, with furnished apartments, board, attendance, and washing.

NOTTINGHAM GENERAL DISPENSARY.—Assistant Resident Surgeon. Salary £140 per annum, all found except board.

QUEEN'S HOSPITAL, Birmingham.—Resident Surgeon for 12 months. Salary £50, with board, lodging, and washing.

RAMSGATE AND ST. LAWRENCE ROYAL DISPENSARY AND THE GENERAL HOSPITAL AND SEAMEN'S INFIRMARY.—Resident Medical Officer, unmarried. Salary £100 per annum, with furnished apartments, board, and attendance. £10 allowed for substitute during annual holiday.

ROYAL INFIRMARY, Newcastle-on-Tyne.—Accident Room House Surgeon for three months. Salary £25 for that period, with board, residence, and washing.

ROYAL SEA-BATHING HOSPITAL, Margate.—Assistant Resident Surgeon. Salary £52 per annum, with board and residence. Apply to the Secretary, Royal Sea-Bathing Hospital Offices, 30, Charing-cross, London.

SCHOOL BOARD FOR LONDON—EVENING CONTINUATION SCHOOLS.—Lecturers and Examiners in First-Aid and Home Nursing. Qualified practitioners (men and women). Apply to the Clerk of the Evening Continuation Schools Committee, School Board for London, Victoria Embankment, W.C.

SHEFFIELD ROYAL HOSPITAL.—Honorary Physician for Mental Diseases.

THE CHIEF INSPECTOR OF FACTORIES gives notice of vacancies as Certifying Surgeons, under the Factories Act, at Bolsover, in the County of Derby; at Market Bosworth, in the County of Leicester at Barnsley, in the County of York; at Arklow, in the County of Wicklow; and at Penshurst, in the County of Kent.

WARRINGTON INFIRMARY AND DISPENSARY.—Junior Resident House Surgeon, unmarried. Salary £100 per annum, with furnished residence and board.

WEST DERBY UNION.—Resident Assistant Medical Officer for the Workhouse, Rice-lane, Walton-on-the-Hill, Liverpool. Salary £100 per annum, with first-class rations, apartments, &c. Subject to statutory deduction. Apply to the Clerk to the Guardians, Brougham-terrace, Liverpool.

WESTMINSTER GENERAL DISPENSARY.—Honorary Physician. Apply to the Secretary, 9, Gerrard-street, Soho.

Births, Marriages, and Deaths.

BIRTHS.

NEILL.—At 46, Melville-street, Edinburgh, on Dec. 31st, the wife of Charles Neill, M.B., of Ranaghat Medical Mission, of a son.

REYNOLDS.—On Dec. 25th, at Silverhowe, College-park, N.W., the wife of B. Gore Reynolds, M.R.C.S., L.R.C.P. Lond., of a daughter

MARRIAGES.

NEWTON—GRAY.—On Dec. 27th, at Marylebone Presbyterian Church, Upper George-street, W., Duncan Gray Newton, M.B., C.M. Edin., Brook-hill, Sheffield, to Janet Mackinnon, daughter of the late Archd. Gray, of Holland-park, W.

PANCKRIDGE-HOULGATE—On Dec. 27th, at the Church of the Holy Redeemer, Clerkenwell, William Panckridge Panckridge, M.B., to Marie Houlgate.

DEATHS.

BURTON-BROWN.—On Friday evening, Dec. 7th, Dennis, son of F. H Burton-Brown, M.B., B.Ch., 3, Via Venti Settembre, Rome, aged 13 months.

POTTER.—On Dec. 30th, John Baptiste Potter, M.D., F.R.C.P., of George-street, Hanover-square, W., aged 61 years.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

THE YARMOUTH PRACTITIONERS AND THE FEES FOR LUNACY CERTIFICATES.

THE members of the medical profession at Yarmouth are well organised and they have made a good fight in regard to the abuses arising out of the medical aid societies. They are now contesting the question of fees paid for certificates of lunacy by the Poor-law guardians. This fee is only half a guinea and the practitioners are demanding a guinea. Recently there was a case of idiocy, but no medical man in the town would give a certificate and the guardians met on Dec. 28th to decide what was to be done. The claims of the medical men were supported by half the board, and the vote on the question resulted in a tie. The chairman, however, gave his casting vote against the proposal that the fee should be raised to one guinea. For the moment nothing further has been done, and, presumably the lunatic is still at large. The question arises whether, out of the many grievances that require redress, this matter is sufficiently serious to fight over. In any case, and in all these contentions, it is very important to secure the sympathies of the general public. Also it is very necessary to make it quite clear that a medical union is not constituted merely for the sake of improving the financial position of medical practitioners. The main purposes are the maintenance of the dignity of the medical profession and the progress of science, because the public at large is, or should be, equally interested with the members of the profession in these matters. Therefore the struggle should be not so much against insufficient remuneration as against those conditions of work which tend to degrade the profession. The practitioners at Yarmouth will, we hope, be able to prove that the public as well as themselves will benefit by the proposed increase in the fees for lunacy certificates.

AN UNDESIRABLE WHISKER.

To the Editors of THE LANCET.

SIRS,—I shall feel much obliged if some of your readers will advise me about the following case. A young lady patient four months ago had an alveolar abscess which she neglected, and the inflammation extended to the cheek, resulting in a large abscess which had to be opened externally. She presented herself the other day with a well-developed whisker on one side of her face. Naturally she is much concerned about this. Would the x-rays be the best mode of dealing with the case, and if so how should they be used? I shall feel much obliged for any suggestions in the matter.

I am, Sirs, yours faithfully,
Jan. 1st, 1901. M.D.

THE CHOICE OF A CEPHALOTRIBE.

To the Editors of THE LANCET.

SIRS,—Will any professional brother specially versed in such matters kindly inform me whether Simpson's cephalotribe (which I possess) would answer every purpose in cases where it should be considered necessary to make use of such an instrument? Dr. Galabin is in favour of Braxton Hicks's form, whereas Dr. Barnes, on the contrary, considers this pattern "too short," but recommends that of Dr. Fancourt Barnes "as the best he has used." Dr. Lloyd Roberts thinks highly of his own invention, whilst Dr. Kidd insists upon there being "no curve" in the instrument; yet these various instruments are all of greater length than Sir James Simpson's.

I am, Sirs, yours faithfully,
Dec. 26th, 1900. G. P.

TOO PERTINENT.

he *Evening News* is responsible for the following story:—

A doctor in the East-end of London had a long blank wall, fronting a big railway station. To him there entered an advertisement contractor with inviting terms for the garden wall as a hoarding. The doctor saw many fees to be had without attendance or medicine. He closed with the offer. But the first morning found a religious maniac had instructed the billposter to affix to the wall, "Thy days are numbered," in letters a foot long. The doctor considered the warning to his patients as too pertinent, and withdrew from the contract.

INCOME-TAX PAYMENTS.

To the Editors of THE LANCET.

SIRS,—With the income-tax at 1*s.* in the pound the amount payable by persons of even small means is very considerable, being one-half more than last year. It is therefore the more necessary to ascertain without delay whether or not it is possible to obtain a reduction in the amount payable, or, where the tax has been paid, a repayment of a portion. As most of your readers who are engaged in business are now ascertaining the amount of their profits for the year 1900, will you allow us to remind them that if such profits show a diminution they may be entitled to the repayment of a considerable portion of the income-tax paid in respect of the same? Many submit to overcharges, having failed on previous occasions to get their assessments reduced. In most cases the reason why they have failed is that they have not furnished proper accounts, while many have neglected to keep any accounts of their business transactions. If proper accounts be kept, or even if a proper cash account be presented (which is very simple by using the "Taxpayer's Cash Book"), there is but little difficulty in establishing a claim. Thousands of people pay taxes for which they are not liable, more particularly those whose incomes are derived from property and investments where tax is deducted before being paid to the recipients, or when dividends are paid "free of income tax." Where the income of the current financial year has all been received, claims can, in many cases, now be made for four years, and the sum repayable might in the case of private incomes alone exceed £42, to say nothing of tax allowed in respect of life insurance premiums even when the income exceeds £700. We shall be glad to advise any of your readers, gratuitously, whether they can make a claim for repayment if they send us full particulars of their incomes and a stamped addressed envelope.

We are, Sirs, yours faithfully,
THE INCOME-TAX ADJUSTMENT AGENCY, LTD.
12 and 13, Poultry, London, E.C.,
Jan. 1st, 1901.

HOW NOT TO DO IT.

A CORRESPONDENT forwards us the following advertisement which was left in the form of a card upon a patient of his at the same time as similar cards from the butcher and the chimney-sweep:—

SURGERY,
——STREET, ——

Legally qualified and experienced Physician and Surgeon.

HOURS.

Mornings, 9 till 11
Evenings, 6 till 9.
Sunday Evenings, 6 till 7.

Moderate fees.

This sort of thing should not be, and we hope that the "Legally qualified and experienced Physician and Surgeon" will make a note of what we have said. For the present we forbear from mentioning his name.

THE PROVINCE OF THE DRUGGIST.

AN inquest was held on Dec. 26th, at West Hartlepool, upon the body of a female child, aged three years. According to the evidence of the mother, the child had an abscess under her arm. For this she consulted "Mr. Clarkson the chemist," who told her to poultice it and also "gave her something to put on the place." The abscess "healed up nicely," but as the general health of the child was not good she went to Mr. Clarkson again who "gave her a bottle." The child seemed to be getting on all right but unfortunately she suddenly died. Mr. Clarkson in his evidence said, according to the report in the *Northern Daily Mail* of Dec. 27th, 1900, from which paper we have been quoting, that "he had not considered the child in any danger whatever. ..... When the mother came to him about the child's general health he gave her a soothing bottle. Judging from what he had seen and from what the mother said he thought death must have resulted from failure of the heart's action." A verdict was returned accordingly. It is not suggested that Mr. Clarkson's "something to put on the place" or his "soothing bottle" did actual harm to the baby, but, judging from the account of the case given by our contemporary, the druggist clearly went out of his province, which is always a very dangerous thing to do.

MEDICAL QUALIFICATIONS.

To the Editors of THE LANCET.

SIRS,—It is, of course, conceded that medical practitioners who have graduated as "Doctors of Medicine" from our different universities are legally entitled to add to their names the letters M.D. and to be styled "Doctors." It is also generally understood that Licentiates and Members of the Royal College of Surgeons are addressed as, and styled "Mr.," but the discussion has so far left undecided what is the proper title of the physician—"Mr." or "Dr." Several dictionaries which give an unprejudiced explanation of the title state that the term "Doctor" is used to denote one who treats diseases by means of internal remedies, and the term "Surgeon" one who practises external remedies or manual operations. Hence from this one would gather that all duly licensed practitioners of medicine as distinguished from surgery have the right to be styled "Doctor." I also venture to think that it is not generally known that the Licentiates, Members and Fellows of the King and Queen's College of Physicians, Ireland, are by virtue of the *original* Charter entitled to add M.D. after their names and to be styled "Doctors." A case to test this right was instituted by the University of Dublin *v.* King and Queen's College of Physicians, and heard before the Master of the Rolls. The decision given by this high legal authority was that although the diploma does not *now* entitle the holders to place the letters "M.D." after their names (which had been previously done since the establishment of the College, whose charter confers "the rights, style, title, and precedence of a Doctor of Physic" on its diplomates), yet in his opinion they had the right to the prefix of "Doctor." Another test case was submitted to the Attorney-General (afterwards the

distinguished Baron Deasy of the Court of Exchequer, Ireland) in 1861 as to whether the L.K. & Q.C.P.I. as such, were entitled to the degree of Doctor of Medicine and to use the letters M.D. after their names. His opinion was as follows: "I think the Licentiates and Fellows, as such, of the King and Queen's College of Physicians, are entitled to the degree of Doctor in Medicine and to use the letters M.D. after their names.—Signed, R. Deasy." Though we have no desire to place "M.D." after our names, yet we wish to assert that we have the legal right to the title and prefix of "Doctor," and that while by courtesy it is also usually extended to those who are physicians, yet they have no legal right to affix the title of "Doctor" to their names in documents, visiting-cards, or door-plates unless the charter of their College confers that right upon them. The whole question is based on the assumption that "Doctor" means "M.D.," whereas, as stated above, in most dictionaries "Doctor" means "physician."

I am, Sirs, yours faithfully,

Dec. 31st, 1900. K. & Q.C.P.I.

THE GIVING OF TESTIMONIALS.

A CORRESPONDENT has sent us two cards received from a masseur. The one bears his name, his address, and an intimation that he is "Certificated in Massage, Electricity, and the Nauheim treatment." The other is a copy of a certificate signed by a medical practitioner of Harley-street who is a graduate in medicine of the University of Cambridge and M.R C.P. Lond. It is worded as follows: "This is to certify that on the termination of a three months' course of Lectures and Demonstrations in Medical Electricity, Massage, and the Nauheim Treatment, Mr. —— [the full name is given] passed an excellent examination, and that he is highly qualified to administer these treatments under medical direction." We think it extremely unwise of any medical man to give certificates of this kind. Of course, there is no harm in a medical man recommending any one whom he considers to be a skilled masseur or administrator of electricity to his patients or to other medical men who may be seeking such a person, but it is not fitting that a masseur should have in his possession for general distribution testimonials recommending himself signed by a medical man. The distribution of such cards as those we have referred to advertises the medical man quite as much as the holder of the certificate. Possibly the medical man in question may not be aware of the abuse of his certificate, but now that we have called his attention to the matter we hope that he will take such steps as he should do.

THE LEGALITY OF BRITISH QUALIFICATIONS ABROAD.

To the Editors of THE LANCET.

SIRS,—I shall be very much obliged if you will kindly inform me what are the necessary conditions of practice in Ontario, Canada, and if a holder of the triple qualification dated 1900 would require to take a Canadian qualification in addition.

I am, Sirs, yours faithfully,

Dec. 28th, 1900. H. M. ROBERTS.

*** Practitioners must be registered by the Council of the College of Physicians and Surgeons of Ontario. In certain cases registration is optional on the part of the Council.—ED. L.

MILNE'S BATTIST AND ABSORBENT RIBBON GAUZE.

MILNE'S battist is a thin but strong waterproof fabric, prepared with india-rubber and intended as a substitute for oiled silk or gutta-percha tissue. The manufacturers claim for it that it is grease-proof and spirit-proof, and can be boiled for two hours without injury, thus rendering the same piece fit for use over and over again. It is said to withstand all antiseptics and to be imperishable and non-adhesive in any climate. Milne's sterilised absorbent ribbon gauze is used for the plugging of wounds and cavities in surgical operations, for which purpose it is made very soft and has a woven edge to prevent fraying. It is supplied in several widths and either medicated or plain as desired. These dressings are made by Mr. John Milne, the Galen Manufacturing Company, Ladywell, London, S.E.

THE QUESTION OF THE COMMUNION CUP.

To the Editors of THE LANCET.

SIRS,—The Vicar of Wragby, the Rev. E. H. Sankey, has written to the *Yorkshire Post* to point out that the danger of infection from the chalice is nothing like so great as that from the universal practice of kissing. "When people," he writes, "are prepared to abandon this it may be worth while to consider the possibility of making some change in the present way of administering the chalice." The Vicar of Wragby forgets that people with sore mouths are not likely to wish either to kiss or to be kissed. Such persons can abstain from kissing, but all cannot abstain from communicating with a good conscience.

I am, Sirs, yours faithfully,

Dec. 29th, 1900. M.B.

HOSPITAL APPOINTMENTS AND ADVERTISING.

IT appears that there was recently a vacancy for the post of surgeon to the Jessop Hospital for Women at Sheffield. Naturally this post is sought after, but we must confess that we were surprised to see in the *Sheffield Daily Telegraph* of Dec. 18th, 1900, an advertisement on page 4 covering one-third of a column in which the candidature, qualifications, and testimonials of a medical man, an aspirant to the post, were set out in full. A similar advertisement from another candidate covering over half a column appeared in the same journal for Dec. 20th, 1900, upon page 1. The gentlemen seeking the appointment were both University graduates, and judging from their testimonials singularly able and intelligent men. But we do not think that for a medical man to state his name, address, qualifications, and the work that he has done, in the advertisement columns of a lay, or, indeed, of any other journal is at all fitting. It is possible that the advertisements were inserted by the board of the hospital, or it may be that it is a rule of the hospital that when a vacancy occurs the candidates should be compelled to advertise in this way. If so, the sooner the rules are altered the better.

Jock.—The amount of public advertisement advisable where a man changes his address and desires to signify this to his patients must be left to the advertiser's taste. We can only say that it should be small and that the issue of a printed notice to all the patients on his books is a preferable proceeding. A newcomer starting in practice should not advertise the fact at all in the newspaper. He has no patients of his own on his books in the locality and the advertisement is therefore directed entirely at those of his fellow-practitioners.

Turicensis.—Dr. Conan Doyle's book "The Great Boer War" will probably meet our correspondent's wants. See our review of this work in THE LANCET of Dec. 22nd, 1900, p. 1815.

J. L.—We do not recommend individual practitioners.

M.B., B.Ch.—There is no harm in accepting the offer.

Victor must consult his family medical attendant.

F.R.C.S. has taken the safer course.

COMMUNICATIONS not noticed in our present issue will receive attention in our next.

Medical Diary for the ensuing Week.

OPERATIONS.

METROPOLITAN HOSPITALS.

MONDAY (7th).—London (2 P.M.), St. Bartholomew's (1.30 P.M.), St. Thomas's (3.30 P.M.), St. George's (2 P.M.), St. Mary's (2.30 P.M.), Middlesex (1.30 P.M.), Westminster (2 P.M.), Chelsea (2 P.M.), Samaritan (Gynæcological, by Physicians, 2 P.M.), Soho-square (2 P.M.), Royal Orthopædic (2 P.M.), City Orthopædic (4 P.M.), Gt. Northern Central (2.30 P.M.), West London (2.30 P.M.), London Throat (2 P.M.).

TUESDAY (8th).—London (2 P.M.), St. Bartholomew's (1.30 P.M.), Guy's (1.30 P.M.), St. Thomas's (3.30 P.M.), Middlesex (1.30 P.M.), Westminster (2 P.M.), West London (2.30 P.M.), University College (2 P.M.), St. George's (1 P.M.), St. Mary's (1 P.M.), St. Mark's (2.30 P.M.), Cancer (2 P.M.), Metropolitan (2.30 P.M.), London Throat (2 P.M. and 6 P.M.), Royal Ear (3 P.M.), Samaritan (9.30 A.M. and 2.30 P.M.).

WEDNESDAY (9th).—St. Bartholomew's (1.30 P.M.), University College (2 P.M.), Royal Free (2 P.M.), Middlesex (1.30 P.M.), Charing-cross (3 P.M.), St. Thomas's (2 P.M.), London (2 P.M.), King's College (2 P.M.), St. George's (Ophthalmic 1 P.M.), St. Mary's (2 P.M.), National Orthopædic (10 A.M.), St. Peter's (2 P.M.), Samaritan (9.30 A.M. and 2.30 P.M.), Gt. Ormond-street (9.30 A.M.), Gt. Northern Central (2.30 P.M.), Westminster (2 P.M.), Metropolitan (2.30 P.M.), London Throat (2 P.M.), Cancer (2 P.M.)

THURSDAY (10th).—St. Bartholomew's (1.30 P.M.), St. Thomas's (3.30 P.M.) University College (2 P.M.), Charing-cross (3 P.M.), St. George's (1 P.M.), London (2 P.M.), King's College (2 P.M.), Middlesex (1.30 P.M.), St. Mary's (2.30 P.M.), Soho-square (2 P.M.), North-West London (2 P.M.), Chelsea (2 P.M.), Gt. Northern Central (Gynæcological, 2.30 P.M.), Metropolitan (2.30 P.M.), London Throat (2 P.M.), St. Mark's (2 P.M.), Samaritan (9.30 A.M. and 2.30 P.M.).

FRIDAY (11th).—London (2 P.M.), St. Bartholomew's (1.30 P.M.), St. Thomas's (3.30 P.M.), Guy's (1.30 P.M.), Middlesex (1.30 P.M.), Charing-cross (3 P.M.), St. George's (1 P.M.), King's College (2 P.M.), St. Mary's (2 P.M., Ophthalmic 10 A.M.), Cancer (2 P.M.), Chelsea (2 P.M.), Gt. Northern Central (2.30 P.M.), West London (2.30 P.M.), London Throat (2 P.M. and 6 P.M.), Samaritan (9.30 A.M. and 2.30 P.M.).

SATURDAY (12th).—Royal Free (9 A.M. and 2 P.M.), Middlesex (1.30 P.M.), St. Thomas's (2 P.M.), London (2 P.M.), University College (9.15 A.M.), Charing-cross (2 P.M.), St. George's (1 P.M.), St. Mary's (10 P.M.), London Throat (2 P.M.).

At the Royal Eye Hospital (2 P.M.), the Royal London Ophthalmic (10 A.M.), the Royal Westminster Ophthalmic (1.30 P.M.), and the Central London Ophthalmic Hospitals operations are performed daily.

SOCIETIES.

TUESDAY (8th).—ROYAL MEDICAL AND CHIRURGICAL SOCIETY (20, Hanover-square, W.).—Address:—Dr. E S. Reynolds (Manchester): Recent Cases of Arsenical Beer Poisoning (with lantern demonstration).

SOCIETY FOR THE STUDY OF INEBRIETY (Medical Society's Rooms, 11, Chandos-street, Cavendish-square, W.).—3.30 P.M. Council Meeting. 4 P.M. Dr. A. E. T. Longhurst: Moderate Drinking, can it Injure Health? Visitors are invited to join in the discussion.

WEDNESDAY (9th).—HUNTERIAN SOCIETY (London Institution, Finsbury-circus).—8.30 P.M. Clinical Evening.

THURSDAY (10th).—BRITISH GYNÆCOLOGICAL SOCIETY (20, Hanover-square, W.).—8 P.M. Election of Officers for 1901. Specimens will be shown by Dr. Macnaughton Jones and Dr. Purcell. The President: Valedictory Address.

FRIDAY (11th).—BRITISH LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL ASSOCIATION (11, Chandos-street, Cavendish-square, W.).—3.45 P.M. Cases and Specimens will be shown by Mr. Mayo Collier, Mr. Lennox Browne, Dr. Kelson, Dr. W. Wingrave, and Mr. Nourse. Postponed Discussion on Mr. Lennox Browne's Cases of Epilepsy in Relation to Adenoid Growths.

CLINICAL SOCIETY OF LONDON (20, Hanover-square, W.).—8.30 P.M. Papers:—Dr. Sidney Phillips: A Case of Fatal Pancreatic Cyst of enormous size Simulating Ascites.—Dr. F. E. Batten: A Case of Subacute Combined Degeneration of the Spinal Cord in Association with Pernicious Anæmia.—Dr. C. W. Chapman: A Case of Syphilitic Disease of the Aortic Valve.—Dr. H. Thursfield: Rheumatic Periostitis with Subcutaneous Nodules.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

MONDAY (7th).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chenies-street, W.C.).—4 P.M. Dr. J. F. Payne: Consultation. (Skin.)

TUESDAY (8th).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chenies-street, W.C.).—4 P.M. Dr. H. Campbell: Consultation. (Medical.)

WEDNESDAY (9th).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chenies-street, W.C.).—5 P.M. Clinical Lecture:—Mr. M. Morris.

THURSDAY (10th).—CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL (Gray's Inn-road, W.C.).—5 P.M. Mr. Lennox Browne: Obstructions in the Fauces and Naso-Pharynx.

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chenies-street, W.C.).—4 P.M. Mr. J. Hutchinson: Consultation. (Surgical.)

CHARING-CROSS HOSPITAL.—4 P.M. Dr. Green: Medical Cases. (Post-graduate Course.)

FRIDAY (11th).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chenies-street, W.C.).—4 P.M. Mr. R. Lake: Consultation. (Throat.)

During the week marked copies of the following newspapers have been received: *Brighton Gazette, East Daily Press (Norwich), Hull Daily Mail, Dundee Advertiser, Leicester Daily Post, Nottingham Daily Guardian, Wigan Observer, Glasgow Herald, Leeds Mercury, Nuneaton Observer, Bedford Record, Kentish Observer, Midland Counties Herald, Times of India, Pioneer Mail, Cheltenham Mercury, Surrey Leader, Whitby Gazette, Western Mail, Western Morning News, Bradford Observer, Ealing Guardian, Warrington Guardian, Scotsman, Architect, Builder, Citizen, Liverpool Daily Post, Health, Bristol Mercury, Sanitary Record, Yorkshire Post, Hereford Mercury, Poole Herald, Mining Journal, Jackson's Oxford Journal, Birmingham Daily Mail, Beverley Guardian, Normanton Herald, Tewkesbury Record, Belfast Evening Telegraph, Indian Daily News, Rossendale Free Press, Sanitary Record, Towyn-on-Sea Times, Scarborough Post, Northern Daily Mail, Local Government Chronicle, Reading Mercury, City Press, Hertfordshire Mercury, Oswestry Advertiser, Weekly Budget, Montgomery County Times, Blyth News, Alfreton Journal, Local Government Journal, Surrey Advertiser, Australasian Gazette, Wine and Spirit Gazette, Le Courrier de la Presse (Paris), Burton Chronicle, Shrewsbury Chronicle, Ayre Advertiser, Madras Standard, Boston Independent, Crewe Guardian, &c., &c.*

EDITORIAL NOTICES.

It is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITORS," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

Lectures, original articles, and reports should be written on one side of the paper only, AND WHEN ACCOMPANIED BY BLOCKS IT IS REQUESTED THAT THE NAME OF THE AUTHOR, AND IF POSSIBLE OF THE ARTICLE, SHOULD BE WRITTEN ON THE BLOCKS TO FACILITATE IDENTIFICATION.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET *should be addressed "To the Manager."*

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES.

THE INDEX TO THE LANCET.

THE Index to Vol. II. of 1900 which was completed with the issue of Dec. 29th, and the Title-page to the Volume, are given in this number of THE LANCET.

VOLUMES AND CASES.

VOLUMES for the second half of the year 1900 will be ready shortly. Bound in cloth, gilt lettered, price 18*s.*, carriage extra.

Cases for binding the half-year's numbers are now ready. Cloth, gilt lettered, price 2*s.*, by post 2*s.* 3*d.*

To be obtained on application to the Manager, accompanied by remittance.

TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, W.C., are dealt with by them? Subscriptions paid to London or to local newsagents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and *not* to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will ensure regularity in the despatch of their Journals and an earlier delivery than the majority of Agents are able to effect.

The rates of subscriptions, post free, either from THE LANCET Offices or from Agents, are:—

FOR THE UNITED KINGDOM.		TO THE COLONIES AND ABROAD.	
One Year	£1 12 6	One Year	£1 14 8
Six Months	0 16 3	Six Months	0 17 4
Three Months	0 8 2	Three Months	0 8 8

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London and Westminster Bank, Westminster Branch") should be made payable to the Manager, MR. CHARLES GOOD, THE LANCET Office, 423, Strand, London, W.C.

SUBSCRIBERS ABROAD ARE PARTICULARLY REQUESTED TO NOTE THE RATES OF SUBSCRIPTIONS GIVEN ABOVE. **It has come to the knowledge of the Manager that in some cases higher rates are being charged, on the plea that the heavy weight of THE LANCET necessitates additional postage above the ordinary rate allowed for in the terms of subscriptions. Any demand for increased rates, on this or on any other ground, should be resisted. The Proprietors of THE LANCET have for many years paid, and continue to pay, the whole of the heavy cost of postage on overweight foreign issues; and agents are authorised to collect, and do so collect, from the Proprietors the cost of such extra postage.**

The Manager will be pleased to forward copies direct from the Offices to places abroad at the above rates, whatever be the weight of any of the copies so supplied, Address—THE MANAGER, THE LANCET OFFICES, 423, STRAND, LONDON, ENGLAND.

Communications, Letters, &c., have been received from—

Two Clinical Lectures ON ENLARGEMENT OF THE PROSTATE.

Delivered at the Medical Graduates' College and Polyclinic

BY P. J. FREYER, M.A., M.D, M.CH.,
SURGEON TO ST. PETER'S HOSPITAL FOR STONE AND URINARY DISEASES.

LECTURE I.

Delivered on Nov. 2nd, 1900.

GENTLEMEN,—To-day I propose considering with you that condition commonly called "hypertrophy of the prostate," an enlargement of the organ incidental to declining years and which frequently causes obstruction to the urinary flow. It is sometimes named "senile" enlargement, a not particularly appropriate description, as the disease, if it occur at all, sets in long before senility in the general acceptation of that term supervenes, and one that men who have scarcely turned middle life sometimes resent as offensive. As the disease is not a hypertrophy as generally understood, perhaps the most appropriate description would be enlargement of the prostate of declining life, but for brevity we will refer to it simply as "enlargement of the prostate."

It will be convenient in the first instance to briefly recall some of the characteristic features of the healthy organ. The prostate is a glandular body which surrounds the neck of the bladder and the adjacent inch of the urethra. In the adult it is of the size and shape of a chestnut, being about one and a half inches broad, one inch long, and three quarters of an inch deep. Its average weight is six drachms. The base is directed backwards towards the bladder, the neck of which it embraces, and the apex forwards, touching the triangular ligament. The under surface, which is smooth and slightly grooved longitudinally, rests on the rectum, with which it is connected by dense fibrous tissue. The prostate consists of two lateral lobes and a median portion placed at the under and posterior aspect of the organ, between the ejaculatory ducts, which perforate the lower part of the gland obliquely before opening into the prostatic urethra. This median portion is, as a rule, a mere transverse band, but occasionally a rounded prominence is formed in this situation even in the healthy organ, forming a true third or middle lobe, which, as we shall presently see, plays an important rôle in enlargement of the gland. It is to be noted that this median portion lies immediately beneath the neck of the bladder, forming, in fact, its floor.

Structurally the prostate is composed of glandular substance and a stroma made up of muscular and fibrous tissues. The glandular substance consists of follicular pouches with ducts, lined with columnar epithelium. The excretory ducts, from 12 to 20 in number, open into the urethra beside the veru montanum. The muscle forms the bulk of the prostate, its function being to eject the glandular secretion, or prostatic fluid, to mix with that from the ejaculatory ducts.

It is now recognised that the prostate is a purely sexual organ. It has a tendency to increase in size in a large proportion of men after the age of 50 years, but the enlargement does not generally declare itself by any marked symptoms till after 55. This rule does not hold good in India, for it is generally recognised by surgeons in that country that decided symptoms of enlargement of the organ manifest themselves in natives as early as at the age of 45 years. It must be borne in mind, however, that the expectation of life in Orientals is about 10 years less than in Europeans—that is to say, a native of India is at 45 years of age comparatively as old a man physically and sexually as a European is at 55 years. Even in Europe we occasionally meet with instances of true enlargement at an earlier age, but they are not sufficiently numerous to invalidate the general rule laid down.

It is estimated from statistics collected by Thompson and others that about 33 per cent. of men beyond 55 years of age are subject to enlargement of the prostate, but not more than 5 per cent. ever suffer from symptoms.

The overgrowth may be uniform in character, the hypertrophy extending equally to all parts of the gland, which thus preserves its symmetry. This is the form of enlargement that is least liable to be attended by symptoms. But any one or two of the three lobes into which the organ may be divided surgically may assume a more pronounced overgrowth than the remaining portion of the gland. Thus there may be a very marked enlargement of one or both lateral lobes, the middle lobe being scarcely prominent, or there may be an outgrowth of the latter to such a degree as to cause obstruction, or even retention, of urine and no enlargement of the general body of the gland be felt through the rectum. It is the enlargement of the middle lobe that gives rise to the most urgent symptoms. Situated as it is immediately beneath the inner orifice of the urethra, even a small nipple-shaped projection of the median portion may give rise to troublesome symptoms by presenting a valvular obstruction to the flow of urine. This lobe has a tendency to grow upwards and inwards into the bladder, pushing the trigone before it and forming a pyramidal tumour with narrow pedicle, which during micturition falls against the urethral orifice, plugging it somewhat after the manner of the glass ball in a soda-water bottle.

If we examine the enlarged prostate histologically we find that all its constituents are invariably increased, though, as a rule, to an unequal degree. It is not a neoplasm—the microscope revealing no new elements; nor is it the result of inflammatory action. It is an irregular hypertrophy of the organ but not of a compensatory character, no useful purpose being served thereby. Sometimes the overgrowth is mainly confined to the stroma, and particularly to the fibrous elements, thus partaking of the character of a fibro-myoma. As a rule, however, hypertrophy of the glandular tissue predominates to such an extent that some authorities regard the enlargement as an adenoma throughout its whole course, as it would seem always to be in the beginning. The most important feature of the enlargement from a surgical point of view is the presence of localised overgrowths with more or less defined capsules, forming the so-called "prostatic tumours," which may occur in any part of the gland. These are always confined within the capsule of the prostate; though, carrying the capsule before them, they may project from its surface as bosses or form polypoid-like outgrowths projecting into the cavity of the bladder and connected with the main body of the organ merely by a narrow pedicle, which, however, is always composed of true prostatic tissue.

The average weight of the normal prostate being six drachms, one weighing seven drachms is regarded as hypertrophied, and the weight may increase to several ounces. In size the enlarged prostate may reach from anything beyond that of a chestnut to that of an orange, or even of a cocoanut. The urethra and bladder will be altered in shape in accordance with the size and form of the overgrowth. The prostatic urethra is invariably lengthened and may attain to four inches, so that 12 or 13 inches of catheter may be introduced before the urine begins to flow. When the lateral lobes are symmetrically enlarged the urethra is compressed from side to side and on section resembles a vertical slit. When one lobe only is enlarged the urethra, being diverted to the opposite side, will be curved laterally. If the median lobe be hypertrophied the urethra will be curved upwards towards the inner orifice, and if it be very large, pyriform, and projecting into the bladder, there will be a channel on either side, the urethra being Y-shaped. When the overgrowth assumes the form of a collar round the neck of the bladder, as it sometimes does, the urethra will necessarily be contracted at this situation.

The prostate being debarred from expansion in front by the triangular ligament and beneath by the dense fascia between it and the rectum, in its enlargement it gradually advances forwards and upwards in the direction of least resistance. The urethra is carried with it and the inner orifice placed on a higher level than the base of the bladder, which remains stationary. A post-prostatic pouch is thus formed in the bladder which is never emptied of urine during the acts of micturition. This remaining quantity of urine, which is termed "residual," gradually increases in quantity as the hypertrophy progresses and the muscular power of the bladder diminishes, owing to the persistent overstrain that the organ is subjected to in order to overcome the obstruction to the flow of urine. In the early stages of the disease there is a compensatory hypertrophy of the bladder walls to overcome this obstruction, but in time, owing to the

constant straining, atony and dilatation ensue, so that the bladder may contain several pints of urine. The walls may become extremely thin, or muscular trabeculæ may develop, between which the mucous membrane bulges outwards, forming saccules of various sizes. In course of time changes occur in the ureters and kidneys from the backward pressure due to the obstruction of the urinary flow—changes similar to those that have already been described as taking place in connexion with stricture of the urethra. Hæmorrhoids and prolapsus ani also occur frequently in connexion with this disorder from the constant straining in micturition.

THEORETICAL CAUSES OF PROSTATIC ENLARGEMENT.

Many theories have been from time to time put forward to account for the enlargement of the prostate peculiar to declining life, none of which, however, can be said to fit completely with all the phenomena attending this disorder. I shall confine myself to stating briefly the two rival views that at present hold the field.

Guyon and the French school generally maintain that the enlargement of the prostate is not a purely local disease; in that it is merely a local manifestation of a constitutional disorder which commences with general arterial sclerosis and ends in fibroid degeneration; that the genito-urinary organs—prostate, bladder, ureters, and kidneys—are liable to undergo this change in a pronounced form, the muscular and glandular structures being replaced by dense fibrous tissue, but that these latter changes are never independent of general atheroma. The enlargement of the prostate and changes already described as taking place in the urinary tract behind are held to be coincident and not related to each other as cause and effect. It is pointed out in this connexion that all the symptoms commonly regarded as the result of hypertrophy of the prostate may occur when there is no enlargement of that organ as a result of sclerosis of the bladder. Against this theory it is urged that the fact that atheroma and enlargement of the prostate occur together is no proof that the latter is the result of the former—as well might cancer and other diseases which are liable to occur during the atheromatous age be attributed to this degeneration; that enlargement of the prostate occurs when there is no such general atheroma of the system; that arterial sclerosis induces atrophy rather than hypertrophy; that enlargement of the prostate frequently commences before the atheromatous period; and that this enlargement always commences as adenomatous overgrowth and not as fibroid degeneration.

The other theory is that propounded by Velpeau, and at present supported by some of the highest authorities in this country and America, notably Thompson and White—viz., that enlargement of the prostate is analogous to fibroid disease of the uterus. In support of this view it is pointed out that the utricle of the prostate is the equivalent of the uterus (and vagina); that the structure of the prostate and uterus are somewhat similar; that there is a great resemblance in structure, position, and mode of growth between the fibro-myomata found in the uterus and the overgrowths that constitute enlarged prostate; and that the disease in both instances sets in when sexual activity is on the wane and does not originate when that activity has completely ceased. In opposition to this view are advanced the facts that the utricle, which is the true analogue of the uterus, takes no active part in the prostatic enlargement and that the uterine tumours commence as fibro-myomata, whereas the prostatic overgrowths originate as adenomata.

One of the most important effects, from a surgical point of view, of the acceptance of Guyon's theory, if carried to its logical conclusion, would be to prohibit the employment of any form of operative interference aimed at the radical cure of the disease—to limit the treatment, in fact, to the palliative kind. Whatever may be thought of the other view, it offers, at any rate, a plausible basis for active interference, as will subsequently appear.

SYMPTOMS.

We now come to the symptoms of enlarged prostate. A man aged over 50 years consults you because (1) he finds that for some time he has suffered from increased frequency of micturition which troubles him more at night than throughout the day; (2) he has some difficulty in starting the stream; (3) there is diminution in the strength of the urinary flow, which instead of being projected in the normal curve falls directly downwards from the meatus simply by its own weight; (4) he strains to propel the urine onwards, but his efforts have little or no effect in strengthening the stream, but, on the contrary, the straining may arrest the flow completely; (5) there is incomplete stoppage, as indicated by dribbling at the end of micturition; and (6) there may be intermittency of the flow due to the ball-valve action of the middle lobe. If the patient does not complain of pain, beyond perhaps an undefined aching about the perineum, and there is no hæmaturia, the case is in all probability one of enlargement of the prostate in a comparatively early stage. It will be observed that none of the symptoms are referable to the prostate itself. They are attributable to interference with the functions of the urethra and bladder caused by changes in the gland which are so gradual that they do not cause pain like inflammation or malignant disease. As the disease progresses, unless relieved by art, all the symptoms are aggravated and others—notably pain and hæmaturia—supervene.

In the early stages of the disorder the increased frequency of micturition is due to some outgrowth at the neck of the bladder which acts as an irritant, like a foreign body, to this the most sensitive portion of the organ. Local congestion or even inflammation of the mucous membrane ensues and this induces further frequency. Later another factor comes into play: a post-prostatic pouch is formed in which a gradually increasing quantity of urine is retained after micturition. This retained urine is, as we have already seen, termed "residual," and the manner in which it causes increased frequency requires some explanation. The bladder is a reservoir capable of containing a certain quantity of fluid, which is voluntarily discharged at convenient intervals. Let us assume that the quantity passed in 24 hours is 50 ounces and that the capacity of the bladder is 10 ounces. It will thus be necessary to empty the bladder at least five times in the 24 hours. But if, the actual capacity remaining the same, a pouch is formed in the bladder containing, say, four ounces of urine that is never expelled, it follows that the *effective* capacity is reduced to six ounces, so that in order to get rid of the 50 ounces that daily flow into it the bladder must be discharged of these six ounces about eight times. As the pouch enlarges and the bladder walls grow weaker the quantity of fluid permanently retained increases and its *effective* capacity diminished, so that eventually micturition has to take place every half-hour or even less. Indeed, this condition may advance to such an extent that the bladder is incapable of discharging any urine whatever, when we have another symptom—viz., continuous dribbling, the urine passing away by day and night as rapidly as it enters the bladder, but the latter always remaining full. The urine passing in this condition is termed the "overflow" and has to be distinguished from "incontinence," a rare occurrence in certain spinal complaints in which the urine runs away from an empty bladder.

The frequency of micturition is, as already stated, worse at night, or rather towards the latter part of the night, and in the early morning on rising—in this respect contrasting with the frequency due to stone, which is always worse in the day time when the patient is going about. Why this should be so has not as yet been satisfactorily explained. It cannot be due to the recumbent position alone, for it does not occur in the daytime if the patient keeps lying down provided he remains awake. It may, as has been suggested, be due to the fact that during the first sleep of the night the bladder is not relieved for a longer period than usual. Distension of the bladder results, with congestion, giving rise to increased frequency which does not subside for some hours till the congestion has subsided.

The urine in the early stages of the disorder is clear and acid. The quantity will probably be increased and the specific gravity be lowered—changes due to fibroid degeneration of the kidneys met with in elderly persons, particularly when prostatic obstruction is also present. As the disease advances the urine becomes cloudy and gives off a fishy odour. Sooner or later the urine has a tendency to decompose, whether as a contingency of catheterism or otherwise, cystitis sets in, and pus is deposited on the bladder walls in thick flakes. This condition is favourable to the formation of phosphatic calculi which are a frequent complication of enlarged prostate, lying in the post-prostatic pouch or in the cysts formed as already described by the bulging-out of the mucous membrane between the muscular trabeculæ.

DIAGNOSIS.

With the presence of symptoms that point to the probable existence of enlargement of the prostate we proceed to verify

our diagnosis by a physical examination of the urethra and rectum.

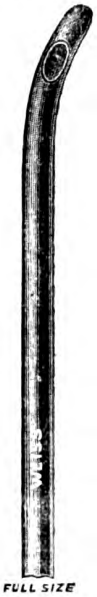
The patient is first directed to pass all the urine he can and we note the strength and general character of the stream. He is then placed on his back on a couch; the glans and foreskin are thoroughly washed with an antiseptic, and a cathether, 13 or 14 of the French scale (7 or 8 E), is slowly and carefully introduced. Our choice of catheters will lie between a Jaques's vulcanised rubber (Fig. 1), a very pliant cylindrical gum-elastic (Fig. 2), or a French coudée (Fig. 3). This latter is, as a rule, the most

FIG. 2.

FIG. 1.

ZE FULL SIZE

FIG. 3.



FULL SIZE

easily introduced. It should be held almost horizontally at first, with the curved point turned downwards, and gradually elevated into the perpendicular position as the instrument passes onwards through the urethra and into the bladder. It should be noted if there be any obstruction at the neck of the bladder and if the end of the catheter rides over it, which would probably indicate an enlarged middle lobe. The quantity of urine drawn off, if any, indicates the amount of "residual" urine. This will vary from a few drachms to three or four pints, according to the stage the disease has reached when the patient first comes under examination. If the quantity be considerable he will express surprise, seeing that he had just previously passed urine and was under the impression that he had emptied his bladder. If the quantity of urine be large the whole of it should not be drawn off at the first interview, lest the patient may faint, or hæmorrhage set in from the vessels of the bladder giving way through loss of their habitual support. If the quantity be moderate a second or third examination should be made to avoid error as to the real amount of the "residual" urine. Before introducing the catheter the hypogastric region should be palpated, for in this way it may at once be recognised that the bladder is distended with urine.

We next make a digital examination of the rectum. The forefinger is greased, the crevice beneath the nail having been previously filled with soap, and introduced slowly and gently to avoid giving pain, and a careful survey of the prostate is made. The extent of the enlargement, if any, should be noted and whether this is general or confined more to one side than the other; whether the contour of the gland is smooth or nodulated; what its consistency, whether soft, indicating adenomatous enlargement, or hard from fibroid overgrowth; also if pressure on the gland gives pain and, if so, to what degree. Much pain with fluctuation would suggest the probability of abscess, particularly if the patient has had fever recently; uterine hardness with nodulation would suggest malignant disease; and a very hard nodule in the substance of the gland accompanied by tenderness on pressure the presence of a calculus in the organ. The finger should pass beyond the gland if possible and sweep the base of the bladder, to ascertain if this is normally soft or hard from sclerosis. Possibly a stone may be felt in the post-prostatic pouch. The examination will be facilitated by making counter-pressure on the abdomen above the pubes with the other hand. The patient should next be placed on his knees on the couch, with his head bent forwards and downwards and the buttocks rendered prominent by the thighs being flexed on the legs. The finger is again introduced and the rectum surveyed as before. This position renders the prostate more prominent in the rectum than the recumbent one and the finger can be introduced farther. The impressions conveyed to the finger in both positions are contrasted and important information may thus be acquired.

Little information with reference to the condition of the middle lobe will be gained by rectal examination. In fact, there may be great outgrowth of this lobe into the cavity of the bladder when no enlargement of the gland is recognised by the rectum. It will, as a rule, be desirable to ascertain the extent and form of the enlargement of the middle lobe. A rough estimate of this can be arrived at by the introduction of a short-beaked sound. When the instrument has entered the bladder the handle is depressed between the thighs and the beak rotated to one side and then to the other, feeling on which side of the instrument the enlarged middle lobe lies and to what extent it projects into the bladder. If the finger be introduced into the rectum whilst the sound is in the bladder a rough idea of the size of the outgrowth may be formed.

Examination of the bladder by the cystoscope will in a large proportion of cases give a still more correct estimate of the size and shape of the middle lobe and as to whether or not it is capable of being removed by operation in a manner that will be described later. At our first visit, however, it will not be advisable to employ either sound or cystoscope. This should always be deferred to a later interview, when the patient should be examined in his own room. At the first visit we rest content with the information gained by the catheter and by rectal examination, taken in connexion with the general symptoms.

After examination the patient should go home and to bed for the day. Indeed, when the case is at all far advanced and the patient feeble it will be advisable to postpone the introduction of even a catheter till he is in his own room.

UNIVERSITY COLLEGE, BRISTOL. — The second annual dinner of the University College Colston Society will take place in the new lecture hall of the college on Jan. 15th under the presidency of Mr. Albert Fry. The guest of the evening will be Sir Michael Foster, K.C.B., M.P., and amongst others Sir William S. Church, Bart., President of the Royal College of Physicians of London, and Canon Ainger will be present. The object of this society is the endowment of Colston chairs in connexion with University College, Bristol, and the assisting of the College in such manner as the committee of the society may approve. In 1900 the sum of £325 was handed to the college by this society.

MEDICAL OFFICERS AT FEVER HOSPITALS.— At the meeting of the Bristol Town Council held on Jan. 2nd the sanitary committee reported that although they had advertised for a resident medical officer for the Ham Green Fever Hospital at a salary of £100 per annum they were unable to obtain any suitable candidate. The committee suggested that the salary be increased to £150 a year, and the town council eventually decided to agree to this proposal, an amendment to increase the salary to £200 per annum being defeated by 38 votes to 30.

PNEUMOCOCCIC ARTHRITIS.

BY EDWARD J. CAVE, M.D., M.R.C.P. LOND.,
PHYSICIAN TO THE ROYAL UNITED HOSPITAL, BATH.

IT would seem that hitherto no observations have been made in this country of the occurrence of arthritis associated with the presence of the pneumococcus in the affected joint, and although the association is probably a very uncommon one, yet, having regard to the comparative rarity of bacteriological examination of morbid fluids, one cannot but suppose that such cases may have occurred and yet escaped detection. The case herein related led to an examination of the literature of the subject, and as some 30 instances are recorded by continental observers there exists sufficient material to form the basis of a fairly complete picture of the disease. The observations up to 1899 have been collected by Dr. L. Leroux[1] of Paris and are embodied in an excellent monograph. These cases, together with three others recorded during the past year, are analysed in the accompanying table. Following Dr. Leroux no account has been taken of records prior to Weichselbaum's[2] observations in 1888, although not a few instances are scattered through the periodical literature of the past century in which arthritis has supervened during or shortly after an attack of pneumonia,[3] and in some of these the clinical accounts are so definite and conform so closely to what we now know of the course of the affection as to leave little doubt of their pneumococcic nature. Noticeably is this the case in some records of Grisolle.[4] Four patients, he says, who had never suffered from any form of articular or muscular rheumatism were attacked either early in the course of a pneumonia or shortly after its subsidence with acute arthritis, affecting in one case the two shoulders, in another the right knee, in the third the left ankle, and in the fourth the right wrist and the left knee. The last case was examined after death and both the affected joints were distended by odourless pus and the synovial fringes were injected. The joint affection was always a continuous one with none of the fugitive character of true rheumatism, and after discussing the relations with this latter disease Grisolle came to the conclusion that the nature of the two affections was quite distinct. He could not, however, exclude the possibility of a pyæmic process. In this country Wilson Fox,[5] after referring to Grisolle's cases, mentions that of a man of dissipated habits who was under the care of Dr. Russell Reynolds for pneumonia. On the day after the crisis there occurred a slight rise of temperature and an effusion into the knee-joint. The pneumonia resolved perfectly, but the arthritis became chronic. These cases occurred prior to the discovery of the pneumococcus and the true significance of the association could not therefore be appreciated. It was not until 1883 and following years that the infective nature of pneumonia, together with the causative agency of the pneumococcus in that disease, was worked out by Talamon, Sternberg, Fraenkel, Weichselbaum, and other observers, and shortly after the earliest publication of this association was discovered the pathogenic efficacy of the same organism in the production of inflammations of various serous membranes and of the joints. Attacks of arthritis associated with pneumococci were recorded in 1884 and 1885, but the first case to be satisfactorily established was that of Weichselbaum which has been already referred to and which was published in 1888. As in the case recorded in this paper the observation related to a suppurative arthritis of the shoulder.

In April, 1900, I was asked to see a man suffering from pneumonia. I found that the patient was a stout, burly farmer, 51 years of age, of alcoholic habits. When I saw him he was moribund. The account of his illness given to me was that he had been seized 11 days before with rigor, pain in his side, and other symptoms of pneumonia, with physical signs of consolidation confined to the lower lobe of the *right* lung. After a severe attack with much delirium crisis supervened on the sixth day of his disease and for 12 hours his temperature was normal or below and his general condition improved. In the evening of the same day his temperature again rose to 103·5° F., violent delirium set in, and on the following day were detected signs of consolidation at the base of the *left* lung. It was on the fifth day of this recrudescence of the disease that I saw him, when he was in a state of coma-vigil, with a pulse of 160 or over, profusely perspiring, with dilated pupils, and evidently near his end. He was too ill to be examined, but on looking at the front of his thorax I was immediately struck with the condition of his left shoulder. This was swollen, deep red, and œdematous, and slight movement of the upper extremity evoked, even in his well-nigh unconscious state, signs of suffering and remonstrance. I was told that five days earlier, [illegible] delirium, and while struggling with his [illegible]ained that his arm had been twisted. [illegible] complained persistently of pain in his [illegible], being delirious for most of the day. On the following day (the third of the injury and ninth of the disease) his shoulder was noticed to be red and swollen and the least movement led to violent exclamations. The condition had persisted, with the appearance of œdema, until the time of my visit. He died within an hour, and shortly after death, no complete post-mortem examination being possible, the skin over the deltoid muscle was seared with a hot iron and a sterilised needle was thrust into the joint. A syringeful of thick greenish creamy pus was drawn off. This contained an abundance of pneumococci, in pairs and short chains of three or four elements, distinctly encapsuled and in pure culture. The leucocytes were polynuclear. The cocci stained well by Gram's method, and were decolourised by Ziehl's solution and partly decolourised in 1 per cent. acetic acid the capsules were very well shown. Typical dew-drop cultures were obtained on agar and blood serum. Its virulence to mice or rabbits was not tested.

This is a very typical case of the acute suppurative form of pneumococcic arthritis and it illustrates many of the ordinary features of the disease; its occurrence as a complication or immediate sequel of pneumonia, its tendency to affect a joint previously damaged by trauma or disease, a "locus minoris resistentiæ," its acute course, its early suppuration, and its commonly fatal event.

Of the 31 cases analysed in the table 23 patients died and eight recovered. The vast majority of the cases occurred in immediate association with pneumonia (28 out of 31), the symptoms of arthritis usually following the onset of the pneumonia at intervals varying from a few days to a fortnight. In two instances (observations of Boulloche and Oliva) the arthritis is said to have preceded the pneumonia by an interval of three days in one case and seven days in the other. Both these cases occurred in children, being the only instances recorded under 30 years of age, and that of Oliva is so unlike most of the other cases in the table that it will be referred to later in connexion with a case of multiple arthritis which the writer has hesitated to include. Three cases are described as occurring independently of pneumonia. The first, related by Griffon[6] in 1896, was that of a woman, aged 71 years, who was admitted comatose with a temperature of 104° F. and a suppurative arthritis of the right ankle. The joint was incised on the same night, but the patient succumbed on the following day. In addition to extensive suppuration in the ankle and calcaneo-astragaloid joints and the neighbouring synovial sheaths, the necropsy disclosed meningitis of the vertex and a recent vegetating endocarditis. Pneumococci were demonstrated in the pus of the affected joint, in the cardiac vegetation, and in the purulent exudation on the meninges. The second case is related by Widal and Meslay[7] in 1896. The patient, an adult male who was the victim of chronic impregnation with lead, complained of dysphagia and arthritis of the first metatarso-phalangeal joint of the left foot; the joint was painful and slightly swollen, and the skin over it was hot and red. The temperature varied from 101° to 102·2° F. At the end of a fortnight the temperature fell and the pain abated, but the patient was mildly delirious and extremely feeble. There was a localised pericardial

[1] Les Arthrites à Pneumocoques, Paris, J. Rousset, 1899. I have made the freest use of the observations collected in Leroux's work.
[2] Ueber seltene Lokalisationen des Pneumonischen Virus, Wiener Klinische Wochenschrift, 1888, Nos. 28–32.
[3] No reference is made here to the well-known association of pneumonia or of physical signs indistinguishable from those of pneumonia at the left base with acute pericardial effusion in the course of rheumatic fever. In the recorded cases the general symptoms and characteristic sputa of pneumonia have generally been absent and the diagnosis made from the physical signs alone. Cf. Southey: THE LANCET, Dec. 9th, 1882, p. 968; Cheadle: THE LANCET, May 5th, 1888, p. 861.

friction rub. Ten days later he died collapsed and the necropsy disclosed a large purulent pericardial effusion, and a sero-purulent collection in the affected metatarso-phalangeal joint. The pus both from the pericardium and the joint contained the pneumococcus in pure culture. The third case, described as occurring independently of pneumonia, is also related by Widal in association with Lesne.[8] A man, aged 68 years, with good previous health except for slight chronic rheumatism of his smaller joints, was seized quite suddenly with a violent chill, headache, fever, and general aching. The next day he had pains in the whole of his left upper extremity. On the following day, the third of his illness, the pain was localised in the left sterno-clavicular joint and the back of the hand, and these parts were red and swollen. He was admitted on the eighth day when his temperature was 102·2° F., and there was an inflammatory swelling over the left sterno-clavicular joint and on the back of the left hand, especially over the third and fourth metacarpal bones. The swelling of the hand gradually abated, but there was still pain when he was discharged six or seven days later. The sterno-clavicular joint suppurated and a small quantity of pus was drawn on two occasions by a sterilised pipette and found to be pure culture of pneumococci. The swelling was slowly absorbed without incision, but there remained some enlargement of the inner end of the clavicle.

The affection is essentially one of adult and advanced life and is far commoner in males than in females (in 28 cases there were 25 males and three females). Both these peculiarities may stand in relation to the predisposing influence of previous damage of the joint, a point to be considered later with the experimental pathogeny of the disease. The age incidence in 29 cases is as follows: from one to 10 years, two cases; from 10 to 20 years, no cases; from 20 to 30 years, one case; from 30 to 40 years, seven cases; from 40 to 50 years, nine cases; from 50 to 60 years, four cases; from 60 to 70 years, four cases; and from 70 to 80 years, two cases. The arthritis is commoner in the upper extremity than in the lower. In 14 cases the upper extremity alone was affected; in 10 cases the lower extremity alone; in the remaining seven there was a multiple lesion affecting joints of both the upper and the lower limbs. In 19 cases inflammation was confined to a single joint; in the remainder two or more joints were involved—viz., in seven instances two joints, in two cases three, and in one case four, while in the two remaining cases the arthritis was multiple and affected more than four joints. With the exception of the hip the larger joints seem more prone to be affected than do the smaller. Thus, of 41 joints affected the sterno-clavicular was concerned four times, the shoulder eight times, the elbow five times, the wrist six times, the metacarpo-phalangeal once, the hip twice, the knee 12 times, the ankle once, and the metatarso-phalangeal twice. In 27 of the 31 cases, one or more of the joints suppurated, in one case the occurrence of suppuration was doubtful, and in three cases there was no suppuration, the fluid effused into the joint being of a sero-fibrinous character. In two or three cases of multiple arthritis the inflammation has been suppurative in one joint and serous in another; this was noticeably the case in the patients of Rendu[9] and of Duflocq and Ledamany.[10] In all of the cases included in the table, with one exception—that of Oliva—the pneumococcus was demonstrated in the fluid in the joints, but cases have been noticed of suppurative arthritis following on a recent attack of pneumonia in which the pus on examination has proved to be sterile. Widal suggests that these cases may none the less be due to the action of the same virus, but that the coccus may have died out at the time of examination; or alternatively, that in these cases with sterile effusion the arthritis may be due to the action of toxins produced by the same organism elsewhere in the body. It is certain that some toxins of microbial origin can induce a suppurative arthritis when injected directly into a joint—e.g., the sterilised culture of the bacillus pyocyaneus (Charrin), and it is conceivable that the toxins produced by the pneumococcus in the lung may have a selective affinity for the joints in certain cases, particularly for a damaged and vulnerable joint, and produce there an arthritis with a sterile purulent effusion. But if we grant so much, how much more probable does it seem that the same toxin may induce a sero-fibrinous exudation, knowing as we do that under certain circumstances and in certain subjects the exudation induced by the living organism itself is a serous (non-purulent) effusion. It is therefore not unlikely that some cases of infective pseudo-rheumatism, characterised by a serous arthritis with sterile effusion, may depend upon the action of pneumococcic toxin. It is well-nigh certain that all the forms of febrile multiple arthritis now commonly classed together as "acute rheumatism" are not of the same nature, and Triboulet and Coyon[11] in their most recent contribution on the subject suggest that while simple uncomplicated acute rheumatism which responds at once to salicin treatment and in which no organisms of parasitic nature have been hitherto demonstrated[12] is due to the action of some unknown virus, the severe cases complicated by visceral inflammations are due primarily to the same unknown virus as the simple cases characterised by fever and arthritis alone *plus* a secondary infection which may be of several different kinds, the bacillus of Achalme in some cases, staphylococci in others, and the much-discussed diplococcus in the majority. We may perhaps class Oliva's case as one of this kind due to the action of pneumococcic toxin, or we may consider it as an ordinary case of acute rheumatism accidentally complicated with pneumonia. The patient was a child, aged eight years, with the symptoms of a febrile polyarthritis which was very slightly influenced by salicylate of soda. The pyrexia did not abate and on the seventh day pneumonia supervened with pneumococci in the sputa. The pneumonia and arthritis subsided together ten days later.[13] Leroux includes this case among those of pneumococcic arthritis on, as it seems, hardly sufficient evidence, and himself admits that the record is too scanty to allow of a positive judgment. It may, however, be compared with the following case in which there was not only clinical evidence of pneumonia, but an organism, which was probably the pneumococcus, was cultivated from the blood.

A woman, aged 24 years, was admitted to the Royal United Hospital, Bath, on March 1st, 1900. She had complained on Feb. 25th, four days before admission, of pain in her chest and indigestion. On the following day she had shivering fits followed by pain in both hips. She went to bed and the pain on the same day affected her ankles, knees, wrists, and shoulders. She had had rheumatic fever three times previously, the first attack 12 years before, when she kept her bed for a month, and the last five years before. On admission her temperature was 102° F., her pulse was 110, and her respirations were 24. She had a flushed face and perspiring skin, with an acid smell. The tongue had a creamy white fur. Nearly all of the joints in her limbs were painful, tender, and swollen, and the more superficial joints were slightly red. The heart's apex beat was in the fifth space in the nipple-line, with a slightly increased force. There was a systolic bruit at the apex and the pulmonary second sound was accentuated at the base. She was ordered 20 grains of sodium salicylate with an alkali every four hours. She remained in much the same condition for the next few days, her temperature ranging between 99° and 101°, and although the physiological effects of the salicylate were quite pronounced there was no abatement of the severe pain in her joints. She was very wakeful at night, and on the third day of admission she had a dose of nitrate of potash and Dover's powder at bedtime, which was repeated the next night, but each time without sleep. She also had five grains of calomel. Her mental state now became odd. She was mostly taciturn, but at times, especially after the visits of her friends, very excited and seemingly hysterical. A week after admission she still complained of the pain in her joints and of slight headache. She would talk continuously in a loud, slow, jerky tone and repeat some statement, usually on a religious topic, over and over again. She passed her urine several times into the bed but the motions were controlled. The urine contained a trace of albumin. There was no optic neuritis.

The salicylate, which had been reduced to 15 grains three times daily when she became delirious, was now replaced by salicin, 20 grains every three hours. Three

[12] The seven cases recently related by Poynton and Paine associated with the presence of a diplococcus were all of severe type and complicated by cardiac inflammation—so severe, indeed, that all but one proved fatal. THE LANCET, Sept. 22nd (p. 861) and 29th, (p. 932), 1900.
[13] Oliva: Rhumatisme et Pneumococcie, Gazzetta degli Ospedali No. 60, 1896.

days later the pains were decidedly less, but she still complained of tenderness in both hands. There had been no further incontinence of urine. She was delirious, at times noisy. On this date (March 11th) was first noted a to-and-fro pericardial friction rub. Her temperature was rather higher, ranging for several days from 102° to 104°. There was more albumin in the urine. There was no perceptible enlargement of the spleen and at no time were there any rose spots on the abdomen. Blood was drawn aseptically from a vein at the bend of the elbow. The skin was washed and scrubbed with soap and spirit lotion, with 0·1 per cent. solution of perchloride of mercury, ether, and alcohol. The skin immediately over the selected vein was frozen with a spray of chloride of ethyl, well seared with a red-hot rod, and perforated by the needle of a sterilised syringe. Ten cubic centimetres of blood were withdrawn from the vein and distributed over a number of agar and blood-serum tubes. From these were grown many colonies of a diplococcus described below. The blood serum at ordinary dilutions showed no clumping influence on emulsions of bacillus typhosus. The red discs numbered 3,900,000 per cubic millimetre and the leucocytes 23,000 per cubic millimetre. On March 13th there were incontinence of urine and fæces, continuous delirium, and some complaint of pain in her head. She frequently tried to get out of bed. There was no optic neuritis. Pericardial friction was still well marked, the heart's apex beating more forcibly and as much as one and a quarter inches outside the nipple-line. The

TABLE OF CASES OF PNEUMOCOCCIC ARTHRITIS.

No.	Observer.	Date.	Sex.	Age.	Relation to pneumonia.	Seat of arthritis.	Nature.	Complications and remarks.	Result.

area of dulness was correspondingly increased. The following day the respirations were from 48 to 54 per minute, there were a troublesome, short, hacking cough and deep orange-coloured expectoration, viscid, and teeming with capsuled diplococci which stained by Gram. There were dulness, tubular breathing, and bronchophony at the left base to two inches above the angle of the scapula. On the 16th her condition had remained practically unchanged with incontinence of urine and fæces as before. The pulse was 136, the respirations were 44, and the temperature was 102·5°. She was ordered four grains of quinia salicylas every four hours. On the 20th, four days later, her general condition showed some improvement, the temperature was lower, about 100°. Pericardial friction was still loud. There were dulness and crepitatio redux at the left base. On the 25th the temperature was still about 100°. The patient was better in herself. There was a little delirium at times and she tried often to get out of bed. The delirium was not worse at night. She complained of slight vertical headache. She was quite rational at the time of examination. She took milk well. The tongue was moist, with a thin white fur. The face was rather flushed. The pupils were equal and active. The heart's apex was in the fifth space, half an inch outside the nipple-line. The impulse was still too forcible. The area of dulness was only slightly increased upwards and outwards. There was a scratching to-and-fro friction over the whole præcordial area except at the apex, where a long systolic bruit was the only sound audible. There were still some dulness and moist sounds at the left base. There were swelling, redness, and tenderness of the knuckles of the left hand, especially of the index finger, and effusion into the right knee-joint with some tenderness. The other joints were free. On March 27th the pericardial friction was much fainter and on the 30th it was no longer audible. The pains had disappeared from the joints. By April 5th she was much better, with a normal temperature for four or five days and no pain. There was no pericardial friction. A long swishing systolic bruit was the only sound audible at the apex and the second sound was accentuated at the base. The urine was now free from albumin. From this date except for a slight recurrence of pain and swelling in the joints of the right arm and hand (from April 8th to 11th) her convalescence was uninterrupted.

This case has not been included in the table as one of pneumococcic arthritis because the identification of the organism cultivated from the blood was not established by animal inoculation. Its cultured characters as tested in broth and in milk and on the surface of blood-agar and blood-serum closely resembled those of the pneumococcus, although it seemed to grow rather more freely than does the pneumococcus when recently isolated, and the colonies on agar presented a slight central opacity or haziness. No growth occurred in the cool incubator, which was kept at 21° C. Morphologically it was a diplococcus, the individual cocci also occurring singly and in short chains. The first cultures, obtained on agar with a plentiful supply of blood, showed the presence of a distinct capsule. The cocci were round or slightly oval, measuring from 0·75 to 1 μ in diameter. They were not typically lanceolate. Treated by Gram's method and stained in the aniline-gentian-violet solution or carbol-crystal-violet for from 30 to 45 seconds only, they retained the stain. The organism differed from the diplococcus isolated by Poynton and Paine by this retention of Gram's stain, by its slightly greater dimensions, and by the distinct presence of a capsule. Triboulet and Coyon, however, in describing the morphology of their diplococcus, which Poynton is inclined to regard as identical with his own, say, "*Ce microbe prend le Gram.*"[14] and, again, speaking of cultures in carbonated milk, "*il n'est pas rare de voir parfois un espace clair donnant une apparence d'encapsulement.*"[15] Unfortunately the case occurred at a season of the year when professional work is heavy, and the cultures died out before an opportunity arose for more careful investigation. Still more unfortunately, working alone in a provincial town the crucial test of animal inoculation could not be applied. The case, therefore, is recorded for what it is worth as one of *severe multiple serous arthritis, with pneumonia, pericarditis, and endocarditis, not influenced by salicylate of soda, and with the presence in the blood of a diplococcus closely resembling (? identical with) the pneumococcus.*

[14] Loc. cit., p. 68.

[15] Loc. cit., p. 67.

Turning now from the consideration of these cases of arthritis in which, while the pneumococcus has been demonstrably present and active in other parts of the body, its presence has not been detected even after skilled examination in the effusion of the affected joints, and reverting to the cases analysed in the table, we find that the mortality has been high, not so much as a direct result of the arthritis, but in relation to other distributions of the pathogenic micro-organism. Of the 31 cases 23 patients died and eight recovered. In the eight recoveries are included two of the cases in which the inflammation was non-suppurative, while the remaining six were attended by suppuration. In five of these recovery ensued after incision and drainage of the joint, while in the remaining case a suppurative lesion of the sterno-clavicular joint was absorbed (the case of Widal and Lesné already referred to).

The association of the arthritis with other localisations of the pneumococcic infection is the rule, and this associated lesion is commonly in a vital part and more directly threatening to life than is the arthritis. The occurrence of pneumonia in 28 out of 31 cases has already been referred to. But often there has been a widespread infection of the system by the virus, with malignant endocarditis (six cases), pleurisy and empyema (five), pericarditis (two), nephritis (three), meningitis (six), and peritonitis (one). In some of the cases there has been a simultaneous inflammation of more than one serous membrane; thus in Leroux's case[16] the necropsy disclosed, in addition to recent endocarditis, a purulent meningitis, pleurisy, peritonitis, and arthritis. This tendency to infect more than one serous membrane at the same time is also pronounced in certain cases of tuberculous and common septicæmic infections, and the associated multiple *seritis* has recently received the name of *polyorromenitis*.[17] The morbid anatomy of the joint infected by pneumococci is essentially that of any other septic arthritis. The presence of the pneumococcus has been demonstrated in all the cases included above save one, that of Oliva, in which it was detected only in the pneumonic sputa. Its identification by chemical, morphological, and cultural characters has in most cases been confirmed by inoculation experiments, and the degree of virulence determined for mice or rabbits. The organism is found in the fluid exudation, either free or embedded in the larger cellular elements, and a thin layer of cocci may exist on the free surface of the fibrinous layer which covers the inflamed synovial membrane. The deeper parts of sections, whether of synovial membrane, cartilage, or bone, show as a rule no micro-organisms. The synovial membrane is thickened irregularly and sections stained by Weigert's method show two layers of about the same thickness; the deeper, vascular and infiltrated with embryonal cells embedded in a meshwork of connective tissue (stained pink with picro-carmine); the superficial, consisting of a network of fibrin arranged for the most part parallel to the free surface and containing leucocytes in the interstices. The leucocytes become more and more numerous towards the free surface and the fibrin less evident, except for a thin layer on the surface itself, this layer containing a number of embedded pneumococci.[18]

In mild cases or those of short duration the synovial membrane alone may be affected, with loss of polish and injection of the fringes. But in many the cartilage is partially or completely eroded and the surface of the bone is laid bare. The changes in the cartilages begin with irritative lesions of the capsules and cells, which are swollen and œdematous-looking, while in some of the cells degenerative changes may be observed with disappearance of the nuclei, the ground substance meanwhile remaining intact.[19] In the older or more virulent cases the changes are much more destructive, the ligaments and cartilages being completely destroyed, as also in some cases the articular ends of the bones. Pus may perforate the capsule and penetrate several inches along the inter-muscular planes or the sheaths of tendons. In the case of Picqué and Veillon[20] it tracked upwards from the knee for six inches along the femoral artery and downwards between the muscles of the calf. One can well understand that in cases which eventually recover the joint is often left with adhesions or

complete ankylosis. The milder cases with serous effusion may, however, leave behind little evidence of the preceding inflammation, and the function of the joint may be perfectly restored.

Reference has already been made to the fact that the arthritis is especially liable to be located in a joint previously damaged, whether by disease or mechanical injury. In the case herein recorded the association with a violent twist of the shoulder-joint was direct and immediate. In two other cases in the table there is the story of a fall on the affected joint shortly before the attack, in one case the shoulder and in the other the knee being affected. One patient had suffered from acute rheumatism, three from rheumatism in a chronic form, and in one of these, while the preceding rheumatism affected the knees and feet only, the pneumococcic arthritis affected the knees.[21] Two other cases were impregnated with lead, in one with the definite discovery of uratic crystals in the cartilage of the affected joint, and one patient had previously suffered from arthritis following typhoid fever. Thus, 10 cases out of 31 gave direct evidence of the situation of the infection in a previously damaged joint. This fact is of interest when we compare it with the experimental investigation of the pathogeny of the affection in animals.

To begin with, we may fairly assume, in the absence of any evidence of external inoculation of the joints, that the virus is conveyed thither by the blood, and there is ample proof of the possibility of this mode of infection. Indeed, it is notorious that in the later stages of severe pneumonia, practically in all cases that prove fatal, the pneumococcus can be directly cultivated from the blood, and the writer has succeeded in doing so in several instances. In these the natural barrier to the production of septicæmia set up by the fibrinous exudation in the alveoli has been broken through with a resulting general infection. The virus circulating in the blood stream, a medium generally unfavourable to the prolonged vitality of parasitic germs, will naturally tend to settle and develop in any part of the economy where the natural defensive mechanisms of the organism are weakened by injury or disease, that is to say, in any *locus minoris resistentiæ*. Widal thus expresses himself on this head[22] "Clinical experience supplies many instances of damage to the joints from internal disorders serving as a gathering-ground for infection. The preceding articular lesions are sometimes clearly in evidence, such as arthritis sicca or the arthropathies of tabes or syringomyelia which become infected by various organisms. Here the predisposition to infection is favoured by the nerve lesion. The experiments of M. Hermann[23] have shown that section of the sciatic nerve predisposed to the localisation of staphylococci circulating in the blood in different parts of the limb which was deprived of its innervation (joints, bone marrow, bursæ, and cicatrices). Recently Kasparek has repeated these researches with cultures of staphylococci, streptococci, and pneumococci[24] and has shown that in animals killed after intravenous injection of the culture, pus containing the injected microbe was already present in the ankle-joint and bone marrow of the tibia on the side of the nerve lesion at the end of 24 hours. In the limb whose nerve was intact, on the other hand, there was complete absence of suppuration or, at the most, the joint contained only a few micro-organisms. Most frequently, however, the explanation of this gathering-ground is not to be discovered, though in some cases careful investigation reveals an unexpected cause. Thus I have recently observed at the Hôpital Beaujon a mon-arthritis of the left first metatarso-phalangeal joint in a confirmed victim of lead impregnation who was attacked by a primary pneumococcal purulent pericarditis. At the autopsy two or three drops of sero-purulent fluid, containing pneumococci in pure culture, could be collected from the joint. By the naked eye no gouty lesion could be detected, but microscopic examination revealed the presence of crystals of urate of soda in the articular cartilages. This solitary localisation in a small joint not usually liable to infection was only apparently fortuitous. The previous uratic deposit led to the succeeding infection. In a word, in this patient attacked by pneumococcic infection the determination to this particular joint was of a 'professional' nature and should be sought in the saturnism which produced the uratic deposit." The same point, together with other details of interest, is brought out by various experiments with the pneumoccus alone. The observations of numerous investigators may be summarised as follows:—1. The injection of a virulent culture of the pneumococcus directly into a joint of a susceptible animal is almost invariably followed by acute suppurative arthritis.[25] 2. The subcutaneous injection of virulent cultures after the previous excitation of an aseptic inflammation in a joint, whether by direct injury or by the injection into the joint cavity of essence of turpentine, gives varying results, in many cases negative (Gabbi), in many positive (Ausset, Zuber). 3 The intravenous injection of virulent cultures with associated aseptic traumatism of a joint leads to arthritis much more certainly than do injections by the subcutaneous method. Finally, Bezançon and Griffon[26] have succeeded in producing an experimental pneumococcic arthritis by modifying the resistance of the animal experimented on in relation to the virulence of the pneumococcus. They find that if a rabbit is first *partially* immunised by the injection of cultures five or six days old and consequently of diminished virulence, and after a few days a full dose of a virulent culture is injected, local lesions are produced rather than a general septicæmia, and especially are these local lesions apt to appear in the joints as pneumococcic arthritis. Leroux, who has admirably summarised these experimental investigations[27] sees in this arthritis after partial immunisation a correspondence with the clinical experience that arthritis usually supervenes after a pneumonia has run its course or towards the end of an attack, when a condition of greater or less immunity has been acquired.

We can deal very briefly with the clinical characters of pneumococcic arthritis. The symptoms may vary in severity from pain and slight swelling limited to a single joint to an intense inflammatory œdema of the whole neighbourhood of the articulation or of a whole limb, with severe pain, heat, and redness, with abnormal mobility from destruction of the ligaments, and with grating of the bared surfaces of the bones. The fever is generally high (from 102° to 104°). The nature of the arthritis can be determined only by its association with pneumonia or other pneumococcic infection and by bacteriological examination of the joint contents. The prognosis is grave both as regards danger to life and the ultimate restoration of function to the joint—in the former respect on account of the extreme frequency of constitutional infection by the pathogenic organism and its characteristic localisations in the endocardium, meninges, and other tissues previously specified. In the cases that recover progress is slow, extending over many weeks, and the function of the joint is as a rule permanently impaired.

Little that is special need be said with regard to the treatment of this particular form of arthritis. In suppurative cases—which, as we have seen, comprise the majority—there can be no hesitation in practising aseptic incision of the joint with flushing, drainage, and fixation, as in any other acute suppurative arthritis. Those cases in which the effusion, drawn off by a sterilised syringe, has proved to be serous or sero-fibrinous in character have generally been treated by fixation on a splint with moderate compression by a bandage over cotton-wool. But even in cases of serous effusion it may be questioned whether an arthrotomy for the removal of the morbid products, avoiding important ligaments and tendons, would not be followed by a speedier cure and more favourable result as regards the ultimate restoration of function to the joint; while at the same time one possible source of generalised infection would be largely removed. In any case convalescence is apt to be tedious and prolonged with much stiffness and adhesion in and about the articulation. This condition must be treated on general principles, by massage, by douches and other hydrotherapeutic measures, or by hot-air baths, and when it seems necessary by forced movements of the joint; in all cases followed by suitable exercises for the restoration of wasted muscles and the preservation of the mobility that has been gained.

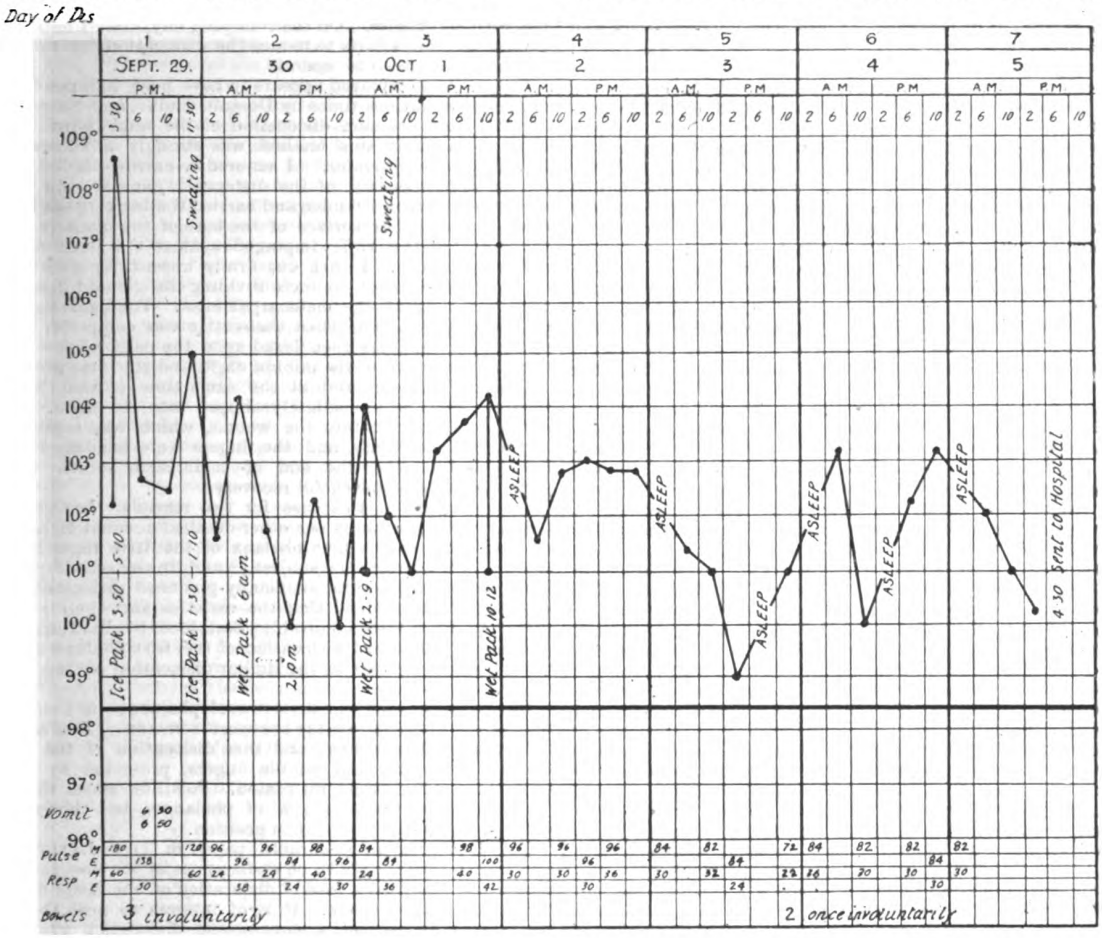
HEALTH OF CARDIFF.—The death-rate of Cardiff during 1900 was at the rate of 13·9 per 1000, which is the lowest of the recorded rates for the 33 great towns.

A CASE OF SIRIASIS.

BY A. E. GRIFFIN, M.R.C.S. ENG., L.R.C.P. LOND.

THE following case occurred in my practice on board ship while passing down the Red Sea. I have adopted the nomenclature of Dr. Sambon and Dr. P. Manson for the condition, described under many different names, of intense pyrexia developed by prolonged exposure to a heated atmosphere, and which is not to be confounded with that of simple "heat exhaustion." Numberless theories have been propounded as to its causation and Dr. Sambon in 1898 suggested that the condition was of microbic origin and he has since stated that the micro-organism has been isolated by foreign observers. In his paper he mentions the fact that stokers on large steam-vessels never show symptoms of siriasis and also suggests that the disease is contracted while coaling ship or stopping along the Red Sea coast.

On Sept. 29th the assistant engineer, a man aged 25 years, had been working in the engine room at a temperature of 114°. He was in good health ate a hearty dinner at one o'clock, went below at 2 P.M. to finish plugging a joint on the top of a boiler, where the temperature was probably 140°, came up at 2.15 P.M. and went to his cabin. At 3.30 P.M. he was found lying unconscious half out of his bunk, still in his boiler suit. When I was called I found the condition of the patient to be as follows: He was unconscious, his limbs were flaccid, his face was cyanosed, his skin was dry and burning to the touch, the pupils were pin-point, all reflexes were lost, the temperature in the axilla was 108·6°, the breathing was shallow and frequent (about 60 to the minute), and the pulse was 180, thin and small. I packed him in an iced sheet, with small pieces of ice round the chest and the neck, and applied ice to the head at 3 40 P.M., and at 3.45 P.M. I injected 20 minims of solution of digitalis over the præcordial area, repeating the same at 4.20 P.M. and again injecting 10 minims at 4.40 P.M. The temperature was taken every 20 minutes in the rectum. He reacted well. He defecated



In the case now reported there seems to be no evidence of focal lesion. The sufferer was an Englishman of good physique, temperate, and a "first-class life," but he had never been in the tropics or at sea before. He was an assistant engineer, and may therefore truly come under the above-named category. After an hour's stay at Suez, where we did not coal, we proceeded direct to Aden, having no communication with the shore meanwhile. It is interesting to note the recovery after a temperature of 108·6° F. Gihon states that there had been only two cases of recovery when the temperature had reached 109°, and seven when 108° and over had been registered out of the several hundreds of cases recorded in America. In the case which I am about to describe I followed Chandler's treatment, as recorded by Manson.

three times involuntarily during the first half hour. The corneal reflex returned at 4.40 P.M. when the temperature had fallen to 104°, the pulse being 122, and the respirations 30. At 5.10 P.M. he moved his arms and legs and became semi-conscious, and as the temperature was then 102·2°, the pulse 120, and the respirations 30 he was removed from the ice-pack, and placed in blankets. At 5.30 P.M. there were paroxysmal movements of the arms and legs. At 6.10 P.M. the temperature was 102·8°, the pulse was 138, and the respirations were 30. The patient was then cold-sponged. At 6.30 P.M. he vomited a large undigested meal, with much frothy mucus, and at 6.50 P.M. he again vomited. At 8 P.M. there were slight convulsions of the limbs. At 9 P.M. the temperature was 103°, the pulse was 120, and the

respirations were 40. The reflexes had returned but they were exaggerated, and it was noted that the chin was turned to the left and the angle of the mouth to the right. At 10 P.M. he showed signs of sweating, and at 11.30 P.M. he was sweating profusely, but the temperature had risen to 105°, the pulse remained at 120, and the respirations had risen to 60. He was again put into the ice-pack till 1.10 A.M. (Sept. 30th), when the temperature had fallen to 101·6°, the pulse to 96, and the respirations to 24, and there was much less cyanosis. He slept till 2.30 A.M., when he spoke for the first time, and again there was profuse sweating at 4.45 A.M. At 6 A.M. the temperature was again 104·2° (in the axilla), with a hot and dry skin, and the patient was wrapped in tepid sheets and ice was applied to the head. At 10 A.M. the temperature was 101·8°, the pulse was 96, and the respirations were 24. He was now seen by Major Hojel, I.M.S., and Dr. Miley of the Coolie Emigrant Service, in consultation. He was then conscious, answered questions said he had no pain, and wanted to sleep. Five grains of calomel and five grains of sulphate of quinine in solution were injected hypodermically and an ice-bag was applied to the head. At 2 P.M. the temperature had fallen to 100° and the patient was put in blankets. He took iced milk-and-soda well at frequent intervals. At 6 P.M. the temperature was 102·4°. Three grains of sulphate of quinine were injected and the patient was again put into tepid sheets till 10 P.M., when the temperature was 100°. He had passed urine involuntarily at frequent intervals all day, the urine having a characteristic odour. On Oct. 1st the temperature was 104° at 2 A.M. The patient was put in the wet pack till 9 A.M., when the temperature was 101°. All reflexes were normal and he complained of no headache or pain. The head was shaved on this day. He was given 20 grains of bromide of ammonium with diaphoretics every four hours. At 10 P.M. the temperature was 104·4° and the patient was in a muttering and semi-delirious condition. He was wet-packed till 12 P.M., when the temperature was 101°. On the 2nd the temperature at 10 A.M. was 102·8°. There were rhonchi and râles over both sides of the chest. A red patch over the sacrum due to constant dribbling of urine was treated with spirit and a powder of equal parts of boric acid and sulphate of zinc. At 10 P.M. the temperature was 102 8°. There was muttering all day, but it was easily controlled. There was herpes of the right cheek, perhaps due to the ice. On the 3rd the temperature at 10 A.M. was 101°. The patient was icteric. He was muttering and picking his fingers. He had been out of bed. His tongue was yellow and drier and there was sordes on the teeth. The bromide was omitted, and 10 minims of oil of turpentine were given every four hours, and boric acid lotion was applied to the eyes. On the 4th the temperature was 100°. The muttering continued, but he was more amenable. Two motions were passed, the first involuntarily. In the evening the patient was in much the same condition. On the 5th the temperature was 101°, but the patient was more conscious and brighter. During the afternoon, the vessel having arrived at Bombay, he was removed to the European hospital, under the care of Lieutenant-Colonel Boyd, I.M.S.

Four days after the removal of the patient to the hospital the temperature became normal and he gradually improved till a fortnight later when, though perfectly conscious during the day, he was still restless and passed urine involuntarily during the night. It was thought advisable to leave him to regain strength in hospital before again subjecting him to the heat of the Red Sea. After he had recovered sufficiently he returned to England, where he arrived at the end of November in good health. The only thing abnormal elicited on examination was that there existed some tremor of both the upper and lower extremities. The knee-jerks were under normal, that of the left being comparatively more active than that of the right.

CARDIFF INFIRMARY.—£6300 have been collected during the past six weeks towards defraying the adverse balance of the Cardiff Infirmary, which amounts to £11,000.

DORSAL DISLOCATION OF THE FIRST PHALANX OF THE LITTLE FINGER;

REDUCTION BY FARABŒUF'S DORSAL INCISION.

BY HAROLD L. BARNARD, M.S. LOND., F.R.C.S. ENG.,
ASSISTANT SURGEON TO THE LONDON HOSPITAL.

ON May 12th, 1900, my house surgeon, Mr. Meredith, told me that he had admitted to the Seamen's Hospital an engineer's fitter, aged 19 years, with a backward dislocation of the first phalanx of his left little finger. He had been standing with his hand resting upon an iron plate so that the head of the metacarpal bone of his little finger was placed over a hole in the plate. A heavy hammer had then fallen upon the back of his hand driving the head of the metacarpal bone downward and completely dislocating the first phalanx backwards. On the same night Mr. Meredith made prolonged efforts to reduce the dislocation under deep anæsthesia but without success. On the following day, after I had made several vigorous efforts to reduce the dislocation by manipulation, I was forced to operate.

The method employed appears to have been independently suggested at various times by Desault, Hulke, and Farabœuf, for the more common dislocation of the same joint in the thumb. Recently this method was strongly advocated by Mr. Hutchinson, junior.[1] I entered a narrow-bladed knife on the dorsal surface of the dislocated joint to the ulnar side of the extensor tendon and carried the back of the blade along the articular surface of the base of the phalanx until the point of the knife impinged against the back of the metacarpal bone. I then cut firmly upward for a distance of about one-third of an inch, dividing the glenoid ligament upon the back of the metacarpal head. The ligament was distinctly felt to give when the section was complete. The metacarpal bone was then flexed upon the palm of the hand to relax the flexor brevis minimi digiti and the first phalanx was hyper-extended and at the same time carried bodily forward, when it immediately slipped into its place. One stitch was inserted into the wound, which was somewhat larger than necessary, and the fingers were bandaged in a flexed position over the end of a forearm splint. The patient made an uneventful recovery.

I have recorded this case for two reasons. In the first place, I have found only one other detailed account of a case of dislocation of the first phalanx of the little finger in the English literature of the subject;[2] and, in the second place, in dissections of several artificially-produced dislocations of this joint I have found that the varieties and their appropriate treatment so admirably described by Farabœuf in the case of backward dislocation of the first phalanx of the thumb apply *in toto* to the similar dislocation of the little finger.

Of dislocations of the first row of phalanges in the hand that of the thumb is by far the most common. That of the index finger comes next, and then dislocation of the little finger. The ring and middle fingers, protected by their fellows are very rarely dislocated. Poisillon states that of dislocations of the first row of phalanges two-thirds are dorsal and one-third palmar in position.

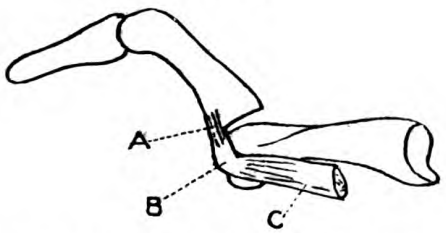
Mr. Battle in an admirable paper in THE LANCET of Dec. 22nd, 1888 (p. 1223), on dislocations of the first row of phalanges, describes a case of dislocation of the little finger very similar to the above. It is of interest to note that in the case of his patient, a stone-mason, dislocation was produced by a stone falling upon the back of his hand. Reduction was, however, effected by manipulation. In another case of Mr. Battle's the first phalanx of the index finger was dislocated by a blow upon the back of the hand with a broomstick. On the other hand, dislocation of the first phalanx of the thumb is more often produced by falls upon the palm of the hand. We may, therefore, distinguish those dislocations in which the head of the metacarpal bone is driven forward by violence applied to the back of the hand from those in which the first phalanx is driven back by force applied on the palmar aspect. The hand is mechanically in continuity with the radius and not with the ulna, and this would appear to explain why this dislocation is so

[1] Brit. Med. Jour., Jan. 15th, 1898.
[2] Battle: THE LANCET, Dec. 22nd, 1888, p. 1223.

much more common on the radial than on the ulnar side, for in the frequent accident of falling upon the outstretched hand the strain is borne by the radial digits. In this common accident the phalanx is driven back, but on the ulnar side, when dislocation occurs, it is due, as we have seen in two cases, to the head of the metacarpal bone being driven forward.

The anatomical arrangement of tendons, bones, but more especially of ligaments, which makes reduction of the first phalanx of the thumb so difficult in some cases is represented by analogous structures in the little finger, and the ingenious methods recommended by Farabœuf for overcoming these obstructions in the thumb are applicable to the little finger. The tendon of the flexor longus pollicis having slipped off the head of the metacarpal bone, usually upon the ulnar side, has been supposed by some surgeons to clasp the narrow neck of the bone and thus to cause the great hindrance to reduction. In dislocations of the little finger artificially produced I found that the flexor sublimis and profundus tendons slipped to the radial side of the metacarpal head in a similar manner. In neither case, however, does it appear at all likely that difficulty in reduction is due to the hitching of slippery tendons on the rounded head of the bone. Others have held that the hindrance to reduction was due to the globular head of the bone passing forward between the heads of the flexor brevis pollicis which then clasped the narrow neck tightly as the muscle spasmodically contracted, and they supposed that the two sesamoid bones made matters worse by locking into the grooves on either side below the head. This button-and-buttonhole theory suggested the treatment by tenotomy of the outer head of the flexor brevis pollicis and even of both heads where tenotomy of one was not successful. In the little finger the equivalent structures are the two heads of the flexor brevis minimi digiti and the globular head of the metacarpal bone, and these might be supposed to produce equivalent effects, although sesamoid bones are not, as a rule, present in the tendons of insertion of the short flexor of the little finger. Farabœuf, however, basing his opinion on an examination of 100 artificially produced dislocations of the first phalanx of the thumb, taught that although the tendons and sesamoid bones formed the larger part of the constricting ring or button-hole around the metacarpal neck, yet it was the glenoid ligament which was the real obstacle to reduction and that a vertical section of this ligament would at once permit the metacarpal head to slip back from between the heads of the flexor brevis pollicis. The bases of the first row of phalanges are much smaller than the articular surfaces on the heads of the metacarpal bones, so that they can articulate with only a small part of these surfaces at any one time. To supplement this deficiency of articulating surfaces on the phalangeal side a dense apron of fibrous tissue is prolonged forward from the anterior edge of the base of the phalanx to which it is firmly attached. The upper edge of this glenoid ligament is loosely fixed to the front of the neck of the metacarpal bone; on either side it blends with the tendons of insertion of the small muscles passing to the tubercles on the bases of the phalanges and in this part of the ligament in the case of the

FIG. 1.

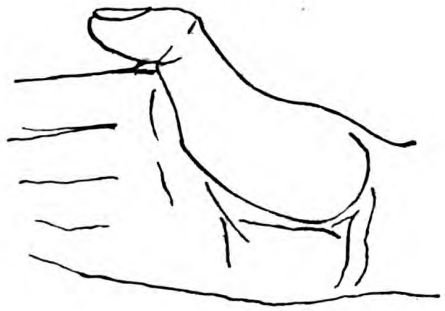


Incomplete dislocation of the first phalanx of the thumb. A, Glenoid ligament. B, Sesamoid bone. C, Flexor brevis pollicis. (Farabœuf.)

thumb the sesamoid bones are found. In short, the glenoid ligament is formed of dense transverse fibres binding together the tendons of the short muscles passing to the bases of the first row of phalanges. When dislocation occurs the phalanx as it passes back carries this apron with it and tears it from its upper attachment. The head of the metacarpal bone passes forward through the rent above the ligament and the sharp, torn edge of the glenoid ligament clasps the neck of the bone firmly behind.

Farabœuf distinguished in the thumb incomplete from complete dislocations and he divided the complete dislocations into simple and complex. In my dissections I have found all these varieties represented in the little finger. In the incomplete dislocations (Fig. 1 and Fig. 2) the glenoid ligament is still in contact with the posterior part of the

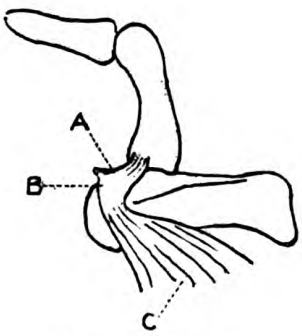
FIG. 2.



The same showing deformity. (Farabœuf.)

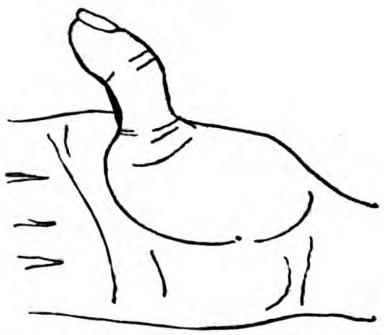
articular surface of the head which has not entirely passed through the rent in the front of the capsule. The lateral ligaments are not ruptured. Reduction is effected easily by pushing the phalanx forward and the head back. In simple complete dislocations (Fig. 3 and Fig. 4) the lateral ligaments are, as a rule, ruptured. The crucial point of this variety is, however, that the glenoid ligament retains its normal relations to the phalanx and extends forward in continuity with the articular surface on the base of the phalanx.

FIG. 3.



Complete simple dislocation of the first phalanx of the thumb. A, Glenoid ligament, B, Sesamoid bones. C, Flexor brevis pollicis. (Farabœuf.)

FIG. 4.



Complete simple dislocation showing the deformity.

The articular cartilage on the phalangeal base rests directly upon the back of the metacarpal bone. This dislocation can be reduced by Farabœuf's method of manipulation. The metacarpal bone is flexed into the palm of the hand, so as

to relax the short flexor. The first phalanx is then hyperextended and carried bodily forward.

Complete complex dislocation was considered by Farabœuf to be the result of ill-directed and violent attempts to reduce a complete simple dislocation by manipulation. In this form (Fig. 5 and Fig. 6) the glenoid ligament is tucked under the

FIG. 5.

Complete complex dislocation showing the deformity. (Farabœuf.)

base of the phalanx so that its articular surface is in contact with that of the phalanx, and it intervenes between the base of the phalanx and the metacarpal bone. In this position the glenoid ligament forms an insuperable obstacle to reduction by manipulation and these are the really difficult cases. To overcome this difficulty Farabœuf suggested to Verneuil that he should make an open incision on the dorsum of the joint and divide the inverted glenoid ligament in the middle line against the back of the head of the metacarpal bone. Verneuil found the method entirely successful in his case. Hulke in "Holmes's System of Surgery" suggested the same method as the result of dissections made by him, but he does not appear to have adopted it in an actual case. Mr. Jonathan Hutchinson, junior, states in a paper drawing attention to this method that it was certainly known as early as the time of the great surgeon Desault.

We may sum up the whole of this matter thus:—1. That dislocation backwards of the first phalanx of the little finger is rarer than that of the index finger and much rarer than that of the thumb. 2. That, unlike the similar dislocation in the thumb, it is probably produced in most cases by violence applied to the dorsal surface of the head of the metacarpal bone. 3. That the three varieties—(*a*) incomplete dislocation; (*b*) the complete simple dislocation; and (*c*) the complete complex dislocation, so admirably described by Farabœuf in the case of the thumb—apply equally to the little finger. 4. That the incomplete dislocation is easily reduced by pushing the phalanx forward; the complete simple form by the method of manipulation suggested by Farabœuf; whilst the complete complex dislocation, the result of ill-directed manipulation, requires the simple operation suggested by Desault, Farabœuf, and Hulke.

Upper Wimpole-street, W.

LITERARY INTELLIGENCE.—Messrs. J. & A. Churchill announce that the "Manual of Anatomy" which the late Professor Alfred Hughes was writing will be published in due course. A large portion of the work was ready before Professor Hughes left for South Africa and it will now be completed and seen through the press by Mr. Arthur Keith, joint lecturer on anatomy at the London Hospital. Many of the illustrations will be from drawings of the well-known dissections exhibited by the late professor.

THE TREATMENT OF DUPUYTREN'S CONTRACTION AND OTHER POINTS IN THE SURGERY OF THE HAND.[1]

BY A. H. TUBBY, M.S. LOND., F.R.C.S. ENG.,
SURGEON TO WESTMINSTER HOSPITAL; SURGEON TO THE NATIONAL ORTHOPÆDIC HOSPITAL; SENIOR SURGEON TO THE EVELINA HOSPITAL FOR CHILDREN.

CONTRACTION of the palmar fascia, or "Dupuytren's contraction," is an affection of insidious onset and slow but sure progress. It so deforms the hand as to seriously interfere with its integrity, and once started it progresses steadily until one or more fingers are brought down and held firmly flexed into the palm of the hand. Beginning usually in the ring finger it spreads to the middle and the little fingers and not seldom to the index finger. Thus, in a patient who came to me recently in the right hand the ring and middle fingers were affected, in the left hand all four fingers, the ring finger in both hands being the most involved. The site of commencement of the thickening of the palmar fascia is generally at the deepest part of the palm of the hand—namely, the transverse crease near the base of the ring finger. From this spot the thickening or induration spreads upwards towards the wrist and downwards towards the fingers. As a rule it affects the lateral prolongation of the fascia on the fingers and occasionally, as in a case I saw recently, the central portion of the digital prolongation is affected.

The exact causes of the induration and contraction of the palmar fascia have never been decided, but there are certain points which stand out quite clearly—viz.: (1) it is more common in the male sex than in the female sex; (2) it is met with generally after 40 years of age; and (3) a large number of the patients who suffer from it have a gouty history. In this connexion it might be mentioned that Mr. C. B. Lockwood found crystals of urate of soda deposited in the affected structures. The question of traumatism is somewhat difficult to speak of, for about 50 per cent. of the patients can trace the onset to a slight injury or repeated rubbing of the palms; whereas, on the other hand, many patients have never been subjected to any manual labour. Therefore the exact cause must remain in doubt unless we are prepared to favour the late Mr. William Anderson's theory that the affection is bacterial in origin and that micro-organisms find their way into the fascia through a wound in the palm. Unfortunately, however, no bacteria have been demonstrated, yet as a fact of some interest we may recall the existence of bacteria or micro-organisms in warts on the hands.

For treatment it has been usual to adopt the method first practised by the late Mr. William Adams of multiple subcutaneous division by a fine tenotome of all the contracted bands of the palm of the hand and of the fingers. This method is fairly successful but it has certain disadvantages. These are as follows: 1. The difficulty often experienced of completely dividing all the bands. If these should extend upwards and over the site of the superficial palmar arch complete division here cannot be effected without danger of wounding the vessels. 2. It frequently happens, therefore, that more than one operation is necessary, as the fingers cannot be fully extended unless the fascia is completely divided. 3. The after-treatment is decidedly tedious and sometimes involves the use of expensive and complicated apparatus. 4. It has been shown that some cases which have been treated by this method recur, much to the patient's disgust and disappointment. So in suitable cases I have operated by the open method—that is to say, I have dissected out all the affected fascia in the palm. It is, however, necessary to carefully select the patient. The urine should be examined for albumin and for sugar, and the patient should be in good health, spare, and one apparently possessing good healing power. The advantages of operating by the open method are as follows. 1. All the affected fascia in the palm can be completely removed and there is no liability to recurrence. A gentleman, aged 66 years, in good health, on whom I operated five years ago by this method, has never shown the slightest sign of trouble and the palm is as soft and flexible as it is possible for it to be. And if

[1] A paper read before a meeting of the British Orthopædic Society on Oct. 13th, 1900.

there be any truth in Mr. Anderson's bacillary theory the best treatment is to get rid of the whole affected part as soon as possible. 2. By the open method treatment is shortened, for as soon as the wound in the palm is firmly healed the use of splints can be discontinued. 3. No expensive apparatus is necessary, thin narrow malleable iron splints being all that are required. Certain disadvantages have been urged against the open method. Firstly, it involves a prolonged dissection, but in itself to a skilled operator this is not a matter of great moment; and secondly, while removal of the indurated fascia in the palm is easy by dissection it is not possible to dissect it out off the sides of the fingers except in strictly localised bands; and, thirdly, if for any reason the hand should go septic after the operation the results are disastrous. It is quite possible, however, that such an event might happen in operating by the older method.

The measures adopted are as follows. The hand is made absolutely aseptic by all the most approved methods and to this point, if the surgeon decides to operate by dissection, he must attend himself and not delegate it to a subordinate or to a nurse; for this is the essence of the whole business and any want of care and forethought in this particular will end in disaster. The same remark applies to instruments and to the accessories. As an anæsthetic I prefer chloroform or the A.C.E. mixture, avoiding ether whenever possible because of the increased hæmorrhage associated with it. An Esmarch's bandage is previously placed around the upper arm so as to prevent the otherwise free oozing from obscuring the field of operation, and the incision is then made vertically over the most prominent band of fascia, extending from the position of the superficial palmar arch to the root of the finger. In extensive cases this incision can be enlarged by carrying out transverse cuts at either end. The dissecting back of the flap of skin is difficult without button-holing it. What happens is that the thickened epidermis peels away from the cutis vera while the latter is attached very firmly by numerous fibrous prolongations to the fascia beneath. Then, too, if the fascia is nodular it often happens that the skin is exceedingly thin, so that great care must be taken in dissecting it away, but it must be turned back as far as the limits of the affection. The next point is the removal of the fascia. Before doing so it is well to define the digital vessels and nerves as they emerge from the divisions and trace them back by cutting through the thickened fascia towards the wrist. The affected structures can now be easily removed and often the finger or fingers can be straightened. In those cases where the fingers are involved a small fine tenotome is passed between the skin and the bands on the lateral aspects and the fibrous tissue divided. An important point is the arrest of hæmorrhage. The Esmarch bandage should be released and whatever oozing occurs should be checked by pressure or by the application of hot sponges. If any arteries spurt it is most advisable to use torsion to check them and not to put on ligatures, for these are apt to give rise to trouble in healing. The application of sutures should be careful and the material to be used is horse-hair. If it happen when the fingers are straightened that there be a hiatus of skin at their roots I have several times performed a small plastic operation and slipped down a little skin to cover up this spot. Sal alembroth dressings are then used and rigid asepsis must be continued until every scab has disappeared. In one of my patients whom I warned on this point considerable trouble followed from neglect. He was a sea-captain and finding that the palm was all but well he took off the dressing and proceeded to climb up the side of the ship by a rope, knocking off a small scab. Acute œdema and trouble in the palm of the hand followed with considerable stiffness and gave him much inconvenience for four months. Subsequently the whole matter settled down and the patient's hand is as good as it can possibly be. The question will arise, Should the hand be put up at once in the straight position? If there is much contraction of the fingers it is better not to do so, because of the pain which arises from stretching of the digital nerves which have become structurally shortened while the finger contracted downwards.

On the whole, then, in suitable cases removal by the open method with the aid of aseptic surgery is a quick and thorough method of dealing with this deformity.

CLUB-HAND.

This is a comparatively infrequent deformity and is almost always congenital. During the last 10 years I do not think that I have seen more than 15 cases and they were mostly unilateral. In some of them the child was born prematurely and there were defects elsewhere. For so unusual a deformity the classification adopted is somewhat intricate, but it is analogous to that of club-foot. The hand may deviate either externally or internally and be either flexed or extended. Hence there are radial and ulnar club-hand and palmar and dorsal club-hand. But it is not often that the deformity is simple, and mixed deviations occur; so that radio-palmar, radio-dorsal, ulnar-palmar, and ulnar-dorsal forms are seen. Morphologically the cases may be grouped thus: 1. The skeleton is complete and otherwise well formed and the malformation consists in a modification of the relations of the articular surfaces and in an abnormal inclination of the line of the joint. 2. The skeleton is complete, but deformed in parts, the radius is often shortened and the carpal bones atrophied. This is the most usual variety. 3 The skeleton is incomplete and deformed. The radio-palmar varieties are generally of this group. There is an absence of one or more bones of the metacarpus or of one of the bones of the forearm. When the radius is absent the ulna is shortened, increased in size, and much curved. The carpal articulation is abnormal and there exist in it numerous fibrous bands and tendons which are in no way related to normal structures. Frequently other irregularities are present in the body, such as absence of groups of muscles or vascular and nerve defects.

Unfortunately, the deformity does not admit of very successful treatment. Passive movements and massage are of service when the patient is young and they are valuable in preventing aggravation of the deformity by contraction of the tendons on the concave aspect of the wrist. Various apparatus have been devised with the object of rendering of the hand useful, but they are not very satisfactory, and the patient can use the hand in many cases to better purpose unfettered by any contrivance. Tenotomy is also of service, and those tendons should be divided which interfere with the placing of the hand in a right line with the forearm and care be taken that important vessels and nerves are not wounded. Dr. L. M'Curdy planned and carried out the following ingenious operation in a radio-palmar deformity with hypertrophy of the lower end of the ulna. He made an incision obliquely across the forearm, beginning upon the dorsum and passing obliquely upwards to the flexor aspect. The tendons on the radial side were tenotomised, the lower end of the ulna was divided obliquely, and to the outer part the semilunar bone was connected with silkworm-gut. In many of the cases which I have seen I have been content to divide the contracted tendons and to gradually improve the position of the hand by massage, passive movements, and a retentive malleable iron splint.

ON THE PROGNOSIS OF TENDON DIVISION AND SUTURE IN THE HAND.

Cases are frequently occurring in surgical practice where division of the tendon has taken place in the hand and failure of complete union followed even after the most careful suture. This is not a mere matter of chance, but it is dependent on certain well-ascertained facts Some of these are the following: (1) the index of tension at which the muscle and tendon are set—i.e., their powers of retraction; (2) the limitation of retraction of the tendon by bands of fibrous tissue binding it in its grooves; and (3) the character of the structures at the spot where division of the tendon occurs—e.g., if division is made where the tendon is surrounded by vascular areolar tissue, plentiful formation of fibrous tissue takes place and the tendon unites despite considerable retraction of the divided ends. It therefore becomes necessary to remember the foregoing three points in forming a prognosis as to the results of tendon-division.

Bearing those points in mind, the seat of election of purposeful division of a tendon for contraction can be determined. It may be of service to give examples. If the extensor tendons of the fingers are severed better results can be expected than in the case of the flexors owing to the closer attachment of the former to the sheaths, the integument, and to one another. But the retraction is greater when division occurs above the wrist than below it. The extensors of the thumb frequently suffer in wounds of the hand. If they are divided at the back of the wrist they retract only about 1 centimetre, as they are more or less bound down by periosteum and good union occurs, but if the division takes place over the metacarpal bone the central end will retract three or four times as much, as the

tendons play freely in the sheath, and the latter is very loosely attached to surrounding structures, so that good union is rare. When the wound is at the metacarpal phalangeal articulation of the thumb the prognosis as to healing is good, for the tendons are bound down to the capsule of the joint and cannot retract even though the joint has been opened.

The flexor tendons, if divided at the wrist-joint, retract very considerably, but the superficial ones less so than the deep, for the former lie in tubes of fasciæ; yet better union occurs here than in the palm of the hand, because the neighbouring structures are more vascular and a good uniting bond of tissue is thrown out. A most important point is to keep the wrist fully flexed for at least four weeks after the accident and then gradually bring the hand into the straight position, taking at least a month to do so. In any operation on the flexor tendons of the hand and fingers the wrist is the seat of election, as it is more likely that new tendon formation will follow, and the exact length of this can be graduated by carefully controlling the position of the hand on the forearm. A recognition of these points is of importance in the treatment of contracted hand for spastic paralysis.

Weymouth-street, W.

LOSS OF THE LEFT FOREARM BY AMPUTATION; DEATH 49 YEARS THEREAFTER; NECROPSY; LOCALISED AREA OF ATROPHY AT THE BASE OF THE RIGHT SECOND FRONTAL GYRUS.

BY PEERS MACLULICH, M.D. DUB.,
ASSISTANT MEDICAL OFFICER, JOINT COUNTIES ASYLUM, CARMARTHEN;
AND
EDWIN GOODALL, M.D. LOND.,
MEDICAL SUPERINTENDENT, JOINT COUNTIES ASYLUM, CARMARTHEN.

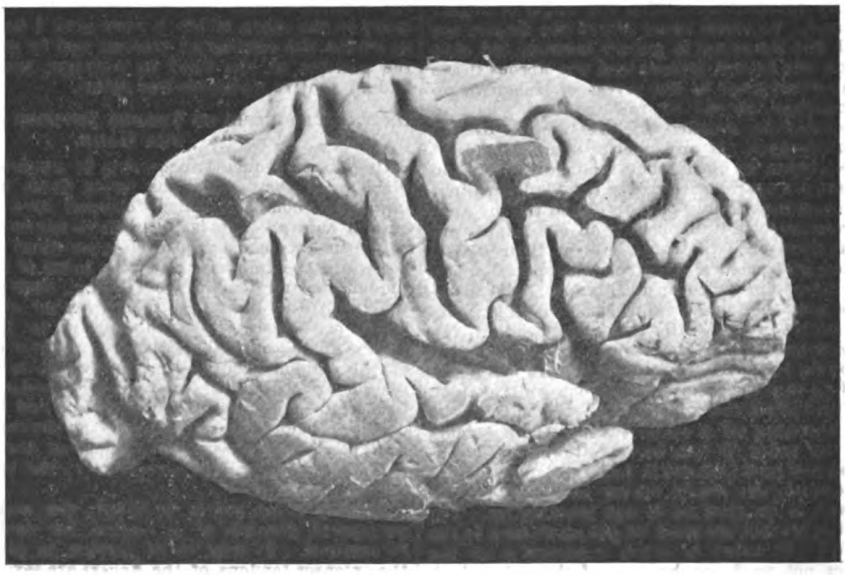
IN the following case we were fortunate enough to get a necropsy and within a few hours of death.

A male, aged 63 years, was admitted to Camarthen Asylum suffering from acute melancholia on May 10th, 1900. The heart was found clinically to be much atrophied. He died suddenly from angina pectoris on May 17th. A post-mortem examination was made 13 hours after death. The cause of death was degeneration of the cardiac muscle.

On admission the patient was found to have undergone amputation of the left forearm just below the elbow-joint (very high up). He had a considerable range of movement in the left upper arm and he used the mutilated limb for holding objects against his side. The history was that when between 13 and 14 years of age a cart went over his left forearm, necessitating amputation. Up to within three years of admission he had been healthy in mind; he first began to show change then, but was not incapacitated. He was of ordinary intelligence and his occupation was that of a post-master and insurance agent at a village. There had never been any fits or convulsive movements. A few days before admission he began to show symptoms of acute melancholia.

At the necropsy, on removal of the pia mater, a patch of softening, roughly oblong, about one and a half centimetres in length and from three-quarters to one centimetre in breadth, was found occupying the grey matter of the brain at the base of the second right frontal gyrus, where it joins the ascending frontal (see figure). It was ochre-coloured. The disorganised tissue was extremely thin and wrinkled, evidently wasted. The lesion looked old, although there was no sclerosis. The subjacent white matter did not appear changed to the naked eye. No lesions were found at any other part of the brain, which was of good consistence. The basal vessels were atheromatous but not at all strikingly so.

The question of interest in this case is whether the shrivelled and softened area in the right cerebral hemisphere bore any relationship to the loss in early years of the left forearm; whether the deprivation in function resulting from such loss had caused the cortical wasting. The area of wasting and softening was well in front of the recognised area for the arm, hand, and fingers, which (as is well known) are placed in the central gyri behind the second and, to some extent, behind the third frontal gyri. As Oppenheim points out,[1] the extent to which the motor region embraces the portions of the frontal (and temporal) lobes bordering upon the motor zone proper (central gyri, paracentral lobule) is doubtful. In all probability the most posterior part of the three anterior frontal gyri must be reckoned in man as well as in the lower animals to the motor region. These outlying parts, however, probably play a subordinate rôle in comparison with that which is to be ascribed to the motor area proper.



The lesion was copied direct on to a Giacomini brain-model and the latter photographed. Circumstances did not allow of photographing the brain itself.

It would be contrary to all experience derived from animal experimentation to correlate the cerebral lesion in this case with the loss of the hand and forearm, on account of the forward position of the lesion. It must be remembered that

[1] Lehrbuch der Nervenkrankheiten, Berlin, 1898.

experience based upon observation in the human being is very meagre. It is curious that such a lesion existed in such clinical conditions, there being no other focus of disease in the brain. That such an isolated lesion, occupying the grey matter, should be due to atheroma is highly improbable.

Carmarthen.

A CASE OF CHRONIC INVERSION OF THE UTERUS OF SEVEN MONTHS' DURATION SUCCESSFULLY TREATED BY AVELING'S REPOSITOR.

BY THOMAS OLIVER, M.D. GLASG., F.R.C.P. LOND.,
PHYSICIAN TO THE ROYAL INFIRMARY, NEWCASTLE-ON-TYNE.

ACUTE inversion of the uterus, if not restored, is said by some authors to be usually fatal. Under all circumstances it is a serious accident. My experience of inversion of the uterus has been gained in consultation with medical friends shortly after parturition in patients, in whom when an anæsthetic has been administered and the exposed surface of the womb has been rendered thoroughly antiseptic, I have had little difficulty in reducing the displacement. On the other hand, I have reported the case of a womb inverted for 18 years becoming malignant; so that, while inversion of the uterus is at all times a serious mishap, there is apparently a certain percentage of women who, once they get over the immediate effects of acute inversion, can go through life with the organ turned inside out without experiencing more than inconvenience.

Of the three different stages into which inversion of the uterus is divided I need not give a lengthened description. They are briefly (1) where the fundus uteri does not come through the os externum; (2) where part of the inverted organ escapes beyond the os; and (3) where the whole womb along with the cervix is inverted.

"Chronic inversion" is the term applied to an acute inversion that has not been reduced or to a displacement which has been slowly brought about by conditions apart from parturition. Inversion, however, is mostly a sequence of parturition and is due to an enlarged and relaxed uterus with well-dilated cervix, upon the fundus of which pressure has been exerted during violent straining, or there has been a precipitate labour and a short umbilical cord, or the accoucheur has pulled too firmly upon the cord while the placenta is still adherent to the uterine wall. Its occurrence after a confinement is usually accompanied by a great amount of shock to the patient and by considerable hæmorrhage. The diagnosis is made by there being no longer felt any fundus above the pubes and in the worst forms by observing the inverted organ, in the form of a globular tumour of the size of a cocoanut, lying between the woman's thighs. The proper treatment at once suggests itself—viz., to replace the uterus under an anæsthetic, having previously taken all antiseptic precautions.

Opinion is divided as to whether if the after-birth is still adherent to the uterus it should be peeled off before attempting to reduce the inversion or whether the uterus should be reduced first and then the placenta removed. It is certainly easier to reduce the inverted organ without the attached placenta, but in peeling off the placenta before replacing the uterus there is often very profuse bleeding. Once the womb is restored the vagina is packed with iodoform gauze. Even where the uterus has been completely inverted after parturition for two or three days and its internal surface has become grey and unhealthy, the discharge escaping from it foul, and the temperature high, yet under thorough antiseptic precautions I have had excellent results notwithstanding the extremely anæmic condition of the patient from loss of blood.

Most of the cases of acute inversion of the uterus are successfully treated at the time; some of the patients, on the other hand, die, while in a few the womb remains inverted. For the present I need only mention that inversion may be also due to a myoma that has passed through a dilated cervix and dragged the interior of the womb down too. Just as hæmorrhage is a symptom of acute inversion, so, also, is it common in chronic inversion. In this form the symptoms are recurrent hæmorrhage along with pain, a sense of dragging, and great discomfort.

A married woman, aged 24 years, was sent to me on Nov. 14th, 1900, by Mr. E. C. Drake of Spennymoor, complaining of pain in the lower part of the abdomen, of frequent losses of blood, and of what she believed to be the womb protruding through the vulva. She stated that she had been confined of her second child on May 1st, 1900, and that a midwife had attended her. The labour was easy and the after-birth came away readily without any traction having been made upon the cord. A few hours after delivery she passed a large clot which was followed by the rather sudden descent of the womb itself, accompanied by a very free escape of blood. Three days after this accident Mr. Drake was called in. Finding the uterus inverted and the patient very ill he tried to replace the organ, but only with partial success; nor was a second attempt the day after followed by any better result. The patient refused to allow any further efforts at restoration to be made and by degrees she recovered from the collapse and from the continuous bleeding. Her recovery, if it ever could be called such, was incomplete, for she began to have recurrent hæmorrhage which at times was rather profuse, and she became unable to attend to her domestic duties. At her menstrual periods the inverted uterus protruded further out of the vulva than in the intervals. She was in great pain and was so inconvenienced by the inverted uterus that she begged to be relieved. The patient was a slim woman and extremely pale and haggard-looking. The heart, the lungs, and the kidneys were healthy. On examination per vaginam the canal was found to be occupied by a pyriform tumour which was felt projecting through a widely dilated os uteri. The narrowed part of the tumour could be traced up inside the os and was found to be continuous with all that remained of the lower segment of the uterus. The sound passed up by the side of the tumour through the os for three-quarters of an inch. As the patient was of rather a spare build the hand could be driven well down into the abdominal cavity behind the pubes but no fundus could be felt. Absence of the fundus above the pubes and the extremely short distance the sound penetrated through the widely dilated os made the diagnosis of chronic inversion of the uterus certain as against that of polypus. The case was not a prolapsed uterus, as was demonstrated to the students in the wards.

At my first examination of the patient I tried to reduce the displaced organ then and there, but it was too painful for the patient. On Nov. 22nd an anæsthetic was administered, when, after having carefully carbolised my hands, and having douched the vagina, I made an attempt both by central and lateral taxis to replace the organ, but although part of the womb could be replaced within the os I did not succeed in returning the whole organ. Failing thus to keep the fundus in its place, I applied Aveling's repositor, packed the vagina with iodoform gauze, and drew together the suspenders of the instrument. The repositor was left *in situ* for three days, Dr. W. Simpson, the senior house physician at the Newcastle Royal Infirmary, tightening the bands daily. When the repositor was removed the inversion had entirely disappeared, the steady and continuous pressure of the repositor having accomplished what forcible taxis failed to do. When I examined the patient on Nov. 28th and the following days no portion of the inverted fundus could be felt in the vagina. The finger could be carried through the os into a well-developed cervical canal nearly one inch in length and the uterine sound now entered to half an inch beyond the bend. The restoration of the uterus was quickly followed by signs of improvement in the general health of the patient. After a further few days' rest in bed she left the infirmary feeling remarkably well with her uterus in the normal position.

Newcastle-on-Tyne.

THE RELATION OF THE BOWEL LESION OF TYPHOID FEVER TO THE GENERAL SYMPTOMS OF THE DISEASE.

BY T. J. MACLAGAN, M.D. EDIN.

THE most prominent of the general symptoms of typhoid fever, that which from first to last is the dominant feature of the illness, is fever, indicated by a rise in the temperature of the body. This rise begins with the onset of the stage of invasion, reaches its maximum often as early as the fourth

or fifth day, and generally by the end of the first week; after the tenth day there is as a rule no further rise, but the final fall of commencing convalescence seldom shows itself before the twentieth or twenty-first day of the fever. The temperature is higher in the evening than in the morning, the maximum range varying from 102° to 104° F. That is the course of the fever in an ordinary typical case of typhoid fever, in which the lesion goes on to sloughing and ulceration, in which no complications arise, and in which we have to deal with nothing except the action of the typhoid bacillus.

In very mild cases in which the inflammation of the intestinal glands terminates in resolution the temperature seldom rises beyond 101° or 102°, and the fever comes to an end in from 12 to 20 days. In severe cases in which the fever lasts for four or five weeks the temperature may remain high during the whole course of the illness. Between the very severe and very mild cases there are all shades and degrees. There is no ailment which presents such protean features as typhoid fever, and no form of fever in which the temperature varies more in different cases. But in uncomplicated cases of typhoid fever the maximum range of temperature is reached before the tenth day, before the local lesion has given evidence of its existence.

How does the bacillus produce the general febrile disturbance? Is the fever merely symptomatic of the bowel lesion? Or is there any other agency at work? How the bacillus acts in producing the bowel lesion we have already seen.[1] We have seen, too, that in its early stages, while affecting only the submucous coat, this lesion gives rise to no local disturbance, no local indications, subjective or objective, by which its existence could be diagnosed, and yet it is at this stage that the temperature attains its maximum. A local lesion which does not cause enough local disturbance to enable us to diagnose its existence is not likely to cause so much general febrile disturbance as is noted at the end of the first week of an attack of typhoid fever. This maximum of fever and minimum of local disturbance, though associated clinically, are not likely to be associated causally. It cannot, indeed, be said that so important a lesion causes no general disturbance and has no share in the production of the fever, but it is evident that its presence is not sufficient to explain and account for the marked rise of temperature noted during the first week of the disease. There must be some other agency at work: but the sole agency with which we have to do is the bacillus. There must, therefore, be some action of the bacillus other than its local action on the intestinal glands, in virtue of which it causes the general febrile disturbance.

In dealing with the action of the bacillus on the intestinal glands we are dealing solely with the action of the parasite on its nidus. But there is also the general action of the organism on the system; and that is what we have to do with in considering the pathogenesis of the general febrile disturbance. The first bacillus which enters the system from without is entirely inert until it is vivified and roused into activity by contact with its nidus in the intestinal glands. Here it is rapidly reproduced and in a short time, as gland after gland is invaded, hundreds, thousands, and ultimately millions of the specific organisms of typhoid fever pass from the nidus into the general circulation through the numerous lacteals and veins with which the affected glands are so abundantly supplied, in a network of which indeed they lie embedded. But be it specially noted that the mass of the organisms which thus pass into the circulation are not mature bacilli but young germs which have just been reproduced, have just entered on their separate existence, and whose organic growth has yet to be completed. Not only in the affected glands but all over the body, in the minute structure of all its tissues, this organic growth goes on and the poison passes from the germ state to that of the mature bacillus. It is the action resulting from the organic growth in the tissues of these millions of organisms that gives rise to the general febrile disturbance associated with the development of the bowel lesion.

The action of the bacillus is thus a dual one: (1) there is the specific local action of the parasite on the intestinal glands; and (2) the general action of the organism on the blood and tissues. The bowel lesion does not cause the fever and the fever does not cause the bowel lesion. They are conjoint results of this double action of the bacillus.

To form a just estimate of the tremendous morbific power of these organisms and of their capacity to produce disturbance we must have some idea of the enormous extent to which they are reproduced and the immensity of the numbers with whose action we have to deal, for it is the vastness of their number rather than the potency of the individual that serves to explain the phenomena to which they give rise. Suppose that each bacillus produced ten others and that one day was the time requisite for the process of reproduction we should from one bacillus have in ten days 1 000,000 000:—thus, on the first day one; on the second day 10; on the third day 100; on the fourth day 1000; on the fifth day 10 000; on the sixth day 100,000; on the seventh day 1,000 000; on the eighth day 10,000,000; on the ninth day 100,000,000; and on the tenth day 1,000,000,000. Let us take a more modest estimate and suppose that each bacillus produced only four others in 24 hours, we should have the following result: on the first day one; on the second day four; on the third day 16; on the fourth day 64; on the fifth day 256; on the sixth day 1024; on the seventh day 4096; on the eighth day 16,384; on the ninth day 65,536; on the tenth day 262,144; on the eleventh day 1,048,576; on the twelfth day 4,194,304; on the thirteenth day 16,777,216; and on the fourteenth day 67,108,864. Even at that rate we should have in a fortnight from one bacillus more than 67,000,000. Suppose 12 instead of 24 hours to be the time requisite for the reproduction of the germs their rate of increase would be doubled. The mind can hardly grasp the number of bacilli which may thus be launched into the circulation.

The action which culminates in this result and in the symptoms of typhoid fever begins at the beginning of the period of incubation, the time at which the poison is received into the system. At first from the paucity of the numbers the rate of increase is comparatively slow and the number of bacilli brought into action is not sufficient to cause disturbance of the system. That is what is taking place during the period of incubation—that is, indeed, what constitutes that period. But it is evident that a time must come when the quantity of poison in the system is so great that it cannot be reproduced four-fold without causing almost an explosion of germs in the system. The onset of this inevitable event terminates the period of incubation and ushers in the stage of invasion. A glance at the figures given will show how certainly this must occur. The reproduction, slow at first, speedily becomes very rapid. Taking the first set of figures the number of bacilli produced at the end of the first five days is 10,000, by the end of the second five it is 1,000,000,000 Taking the second set, at the end of the first week the number is under 5000; by the end of the second week it is over 67 000,000.

It is the organic growth in the tissues of these vast hordes of bacilli that causes the fever and general disturbance noted in typhoid fever. How do they do this? Rise of temperature may be produced in one of two ways: (1) by increased activity of the process by which heat is formed; or (2) by diminished activity of the process by which its formation is inhibited and kept within due bounds. That due to impaired inhibition is illustrated by hyperpyrexia and the increased body heat which results from some lesions of the brain and cervical cord. That due to increased production is exemplified by that with which we are now dealing.[2] But rise of temperature is not the only symptom of such fever. Wasting of the nitrogenous tissues, increased elimination of urea, increased rapidity of the circulation, thirst, dry skin, and scanty urine,—these with rise of temperature are the essential phenomena of fever.

The essential and distinctive feature of an organism is its action on its environment. The action of an organism such as the typhoid bacillus on its environment in the tissues consists in the consumption of nitrogen and water—a consumption which, in virtue of their vast numbers, must be very great. Now when we come to examine minutely into the various phenomena of the febrile state as it occurs in the specific fevers we find that they ultimately resolve themselves into two—increased consumption of nitrogen and increased consumption of water. From these two all the others result. Rise of temperature, quickening of the circulation, wasting of the nitrogenous tissues, increased elimination of urea, thirst, loss of appetite, dry skin, scanty urine all owe their existence to the consumption by the contagium of the nitrogen and water destined for the tissues.

[1] THE LANCET, Dec. 8th, 1900, p. 1639.

[2] See "Fever, a Clinical Study," by T. J. Maclagan, M.D. (J. & A. Churchill, 1888).

For their consumption by these hosts of bacilli represents a direct loss to the tissues. Occurring in the nitrogenous tissues it gives rise to the rapid wasting of these tissues noted during an attack of typhoid fever. Occurring in the brain it causes the headache of the earlier and the wandering of the later stages. Other and necessary results of this consumption by an external agency of the water destined for the tissues are those indicative of a short supply—thirst, dry skin, and scanty urine. The supply may be ample, but it is tapped *en route* by the bacilli and does not reach the tissues in sufficient quantity.

The seat of normal tissue metabolism is the minute structure of the tissues. That, too, is the seat of the abnormal action which we are now considering. Tissue metabolism consists (1) of the taking up of new material from the store albumin, to form fixed or organ albumin; and (2) of the giving off from the tissues of their worn-out organ albumin, which passes back into the circulation and is ultimately eliminated as urea. These actions are simultaneous, neither preceding the other. The bacilli lay hold of the nitrogen of the store albumin at the moment when it is about to be appropriated by, and incorporated in, the tissues as organ albumin. The simultaneous action by which the worn-out organ albumin passes back into the circulation is equally far advanced. Nothing intervenes to prevent this, it goes on only more actively in consequence of the increase of metabolism, and thus is brought about the physiological anomaly that lessened consumption of nitrogen by the tissues is accompanied by increased elimination of nitrogen by the kidneys.

The matter may be briefly put thus: What is the cause of the wasting of the nitrogenous tissues? The consumption by millions of bacilli of the nitrogen destined for their nutrition. What is the cause of the thirst, dry skin, and scanty urine? The consumption by the same bacilli of the water destined for the tissues. What is the cause of the rise of temperature and quickening of the circulation? The increased metabolism which necessarily results from this action going on in the minute structure of the nitrogenous tissues, the chief seat of heat formation. Thus all the essential phenomena of the febrile state as it presents itself in typhoid fever are traceable back to these two agencies—increased consumption of nitrogen and increased consumption of water; and these in their turn result from the action necessarily attendant on the organic growth of vast numbers of bacilli in the structure of the tissues.

Other symptoms noted during the course of the fever are equally explained on this view of the mode of action of the bacillus. The headache of the earlier and the delirium of the later stages of the fever are due to cerebral inanition consequent on the consumption in the brain tissue of the nitrogen and water destined for the nutrition of that organ. The softening of the cardiac muscle and the changes noted in it after death are due to the same cause acting in its structure.

In typhoid fever, as in the other specific fevers, the soda salts are retained in the system or are eliminated in much diminished quantity, while the potass salts are eliminated in increased quantity. The soda salts exist chiefly in the liquor sanguinis; they are retained because the bacilli in taking up the nitrogen and water of the liquor sanguinis take up also the soda salts in it. The potass salts exist chiefly in the tissues; they are eliminated in increased quantity because there is increased tissue disintegration. All these actions go on and all the febrile symptoms continue so long as the bacillus is being reproduced and come to an end only with the cessation of that process. But why does it cease? Why do these organisms not go on growing as long as any nitrogen and water remain for them to consume? And why does anyone ever recover? The fever thus caused comes to an end when the bacilli cease to be reproduced, and their reproduction ceases when the nidus is exhausted, that is, when all the glands which form the nidus have been destroyed. The course of events shows that on an average it takes five weeks more or less for the completion of this process, two weeks occupied by the period of incubation, and three by the febrile stage. Thus all the essential phenomena of typhoid fever, its rise, course, and decline, are causally associated with the life-history of its bacillus in the system.

Recrudescence of the fever.—It has already been pointed out that the intestinal glands are not all affected at the same time and that some reach the stage of sloughing and ulceration, while others more tardily affected are still at the stage of hardening and thickening. It not unfrequently happens that some glands do not become involved in the morbid process till so late in the disease that the fever caused by those already affected is on the decline or may even have come to an end and the temperature be normal before the fresh lesions are sufficiently advanced to add their quotum to the general disturbance. Their appearance on the scene is heralded by a renewed rise of temperature and a recrudescence of the fever. Such recrudescence may occur towards the end of the third week or at any subsequent period. It means fresh glandular lesions, the launching into the circulation of fresh shoals of bacilli and consequent recrudescence of the fever, with a renewal of all the symptoms local and general.

Cases are not uncommon in which, by a repetition of these recrudescences, the fever is prolonged into the fifth or sixth week, it may be without any material addition to the gravity of the symptoms other than that which comes from the prolongation of a disease which is so exhausting and so full of hazards. The latter part of these cases is really made up of a succession of short attacks following each other so quickly that the one almost dovetails into the other. Each is indicative either of the invasion by the bacilli of one or more fresh glands or of a fresh absorption of septic material.

Relapses.—Sometimes the invasion of the latest affected glands is so retarded that instead of an apyretic interval of only 12 or 24 hours we have six or eight, or even 10 or 12, days of apyrexia and apparent convalescence. The fever is then said to relapse. The pathogenesis of the relapse is the same as that of the recrudescence; the difference is the length of the period of apyrexia which separates the second from the first attack. This period of apyrexia is really the period of incubation of the second attack. But the beginning of that period is contemporaneous with the later days of the primary seizure, so that the poison which gives rise to the relapse has really begun its action before the first attack is at an end, and the two, though clinically distinct and separate, are pathologically one.

It has been supposed by some that relapses may be due to errors of diet, to getting up too soon, or to other indiscretion. But the relapse is as truly an attack of typhoid fever as was the primary seizure. Nothing could cause this except the typhoid bacillus. Moreover, the poison which causes it has really begun its action before the first attack is at an end and while the patient was still confined to bed. The relapse is of shorter duration and generally milder than its predecessor. That is what, on this view of its pathogenesis, we might expect, for the field of operation of the bacilli is much curtailed by the destruction during the first attack of so many of the intestinal glands. There is a more scanty nidus, fewer glands to suffer, and a consequent reduction both in the severity of the local lesion and the duration of the febrile symptoms; these seldom last more than a fortnight, often less. The shorter duration is due to the same cause as the lessened severity; there are not glands enough to cause three weeks of fever. But though the relapse is generally milder than the first attack the rule has a good many exceptions, for every now and then a relapse proves fatal. In connexion with this subject it has to be borne in mind (1) that the relapse comes when the sufferer is already weakened by the first seizure; and (2) that one lesion in the bowel suffices for the production of hæmorrhage and perforation and of a fatal issue.

It is mainly in consequence of their shorter duration that relapses are less fatal than first attacks, for the dangers of typhoid fever necessarily increase as the disease goes on. This shorter duration is due to the fact already indicated, that the nidus of the parasite, the field of operation of the bacillus, is materially reduced in extent by the destruction of the glands involved in the first attack.

It is a demonstrated fact that during the relapse glands suffer which had escaped all the risks to which they were exposed during the primary seizure. It occasionally happens that some even run the gauntlet of a second attack without suffering, for second and even third relapses, each with fresh lesions, are not unknown. How come they to escape? How is it possible for any glands to escape invasion by some of the vast number of bacilli reproduced during the course of the fever? Were this poison liquid and equally diffused through the blood it would be impossible for any glands to escape; but it is not liquid and diffusible, but particulate and indiffusible, and therefore not of necessity equally distributed through the blood. The germs reproduced in the intestinal glands may pass into the

general circulation either through the lacteals or through the superior mesenteric vein. But the bacilli in the blood can gain access to the glands only by way of some of the branches of the left or convex side of the superior mesenteric artery. The chance that no bacilli may ever reach some one particular branch of this artery which supplies a given inch or two of the bowel and a given half-dozen glands is quite an appreciable one. The clinical history of typhoid fever and the occurrence of relapses with fresh lesions shows that this chance occasionally becomes a reality.

Such is the explanation of the mode of action of the typhoid bacillus. The local disturbance in the intestinal glands is the result of the reproduction of the parasite in its nidus. The general febrile disturbance is the consequence of the organic growth in the tissues of the millions of organisms thus reproduced in these glands. Neither action would in itself be disastrous or be followed by serious consequences but for the fact that the trouble in the intestinal glands ends in sloughing and suppuration. These two processes bring into play other morbific agencies which are much more potent for evil than the typhoid bacillus. Before the glands slough there are no serious bowel symptoms and nothing to call special attention to the bowel. As already pointed out, the serious bowel symptoms which are apt to show themselves in the later stages of the fever are caused not by the typhoid bacillus but by the various organisms which come into play with the processes of sloughing and suppuration.[3] To the absorption of these organisms into the system are to be ascribed the prolonged duration of the fever in many of those severe cases which run on into the fourth and fifth weeks, the high range of temperature noted in their later stages, and all the alarming symptoms by which it is accompanied. The high fever, the feeble rapid pulse, the dry tongue, the muttering delirium, and general condition of typhoid prostration which characterise the later stages of severe cases are the symptoms not so much of typhoid fever as of septic poisoning. They occur in the advanced stages of bad cases of typhoid fever, but they are due not so much to the direct action of the typhoid bacillus as to that of the various forms of cocci associated with the sloughing process in the bowel. It is the absorption of these into the system and their reproduction there that causes the alarming symptoms of severe cases and makes typhoid fever so serious and so fatal a disease. There are degrees of this as there are degrees of typhoid fever. The sloughs may be comparatively few and come away without giving trouble. The more severe the bowel lesion the more extensive is the sloughing, the deeper the ulcers penetrate into the gut, and the more likely we are to have the poison absorbed into the system.

Gangrenous ulceration in any part of the body is apt to cause septic poisoning; that is, indeed, the chief danger of such ulceration. The risk of this is specially great in typhoid fever, first because the number of ulcers and consequent foci of absorption are so numerous, and second because the affected glands are situate in a network of veins and lacteals whose function it is to take up and carry into the system the materials presented to them.

Though all the symptoms of typhoid fever are ultimately to be traced back to an action set agoing by the typhoid bacillus, not one of its serious symptoms or special dangers is due to the direct action of that bacillus. The dangers attendant on the bowel lesion, diarrhœa, hæmorrhage, and perforation result from the destructive action on the mucous, muscular, and peritoneal coats of the organisms associated with the processes of sloughing and suppuration. The alarming general symptoms which are noted in the later stages of severe cases —high temperature, feeble cardiac action, delirium, and prostration—are due not so much to the growth in the tissues of the typhoid bacillus as to the superadded growth of the millions of cocci which are absorbed into the system from the sloughing glands by the veins and lacteals among which these glands are embedded.

ST. GEORGE'S HOSPITAL.

A CENTRAL TUMOUR OF THE SHAFT OF THE RADIUS TREATED BY ENUCLEATION.

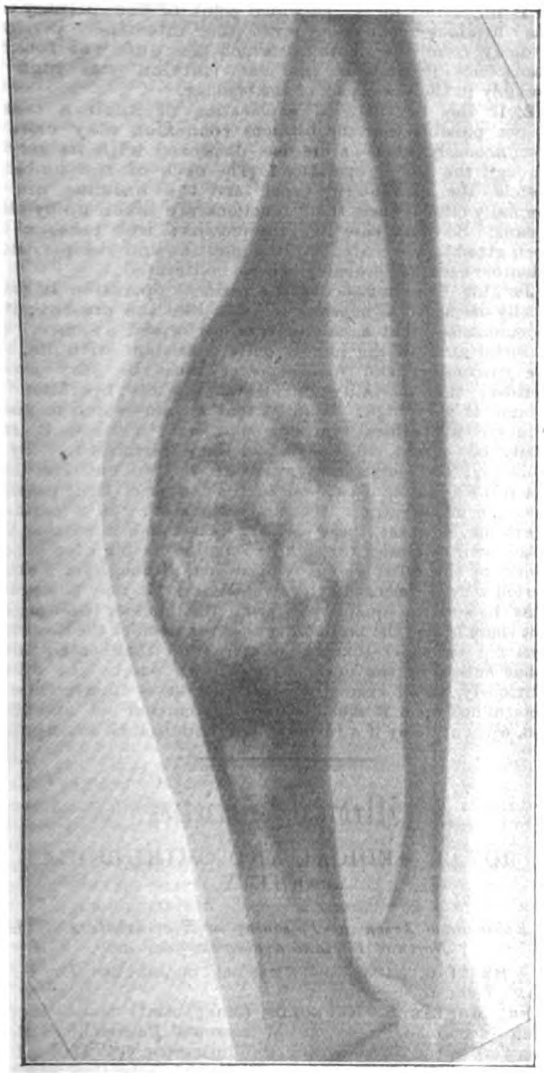
(Under the care of Mr. MARMADUKE SHEILD.)

THE advisability of the employment of enucleation for the treatment of a tumour of bone must depend chiefly on the nature of the growth. For non-malignant tumours this operation may safely be performed, and it is applicable even to cases of central chondromata, in which formerly amputation was always considered necessary. But in any form of malignant growth there is great risk of recurrence. And although in some cases of myeloid sarcoma no recurrence has been recorded after enucleation this must sometimes be due to the case having been reported soon after the operation. Still a sufficient number of cases have been put on record in which the less malignant forms of malignant growths occurring in the interior of bones have been treated by enucleation, and no recurrence has occurred even after several years. The treatment is therefore advisable whenever the slowness of growth or the microscopic structure of the tumour suggests that the malignancy is slight. For the notes of the case we are indebted to Mr. C. R. Keyser, F.R.C.S. Eng., surgical registrar.

A small, spare, and excessively anæmic woman, aged 19 years, was admitted into St. George's Hospital on Sept. 18th, 1900, under the care of Mr. Marmaduke Sheild, suffering from a tumour of the right forearm. The history was as follows. Ten years ago, whilst swinging on a ladder, she twisted her right arm and "broke a small bone." On the removal of the splints some weeks later the swelling which she on admission complained of was discovered. It had gradually increased in size and gave rise to pain at times in the arm and fingers. She was positive that the tumour was of 10 years' duration. On examining the right forearm there was an oval-shaped tumour, obviously an enlargement of the radius, about midway between the elbow and the wrist, but projecting mostly towards the radial side of the arm. It was of stony hardness, with some increase of heat on the surface, and there were many dilated veins coursing over it. It was not adherent to the skin, and no softening, bruit, pulsation, or egg-shell crackling could be detected. In length it measured three inches and the circumference at its widest part was seven and a half inches. The muscles of the forearm and hand were somewhat wasted, but she stated that the right hand was just as useful and as strong as the left. Aching pain was constantly present. It was thought at "consultations" that the tumour was either a very slowly growing (so-called) myeloid sarcoma, an enchondroma, an old fracture with excessive formation of bone, or some rare form of osseous cyst, such as hydatid or sanguineous cyst, but in any case that it ought to be explored and dealt with according to what was found.

On Oct. 4th, ether having been given, Mr. Sheild applied an Esmarch's bandage to the limb and then made an incision about five inches long on the radial side of the tumour on its dorsal aspect and exposed the bone and trephined it. The wall of the tumour was very thin and its cavity was partially divided up into loculi by thin bony septa. These can be well seen in the striking skiagram which was taken at the hospital by Mr. Addyman in charge of the Roentgen-ray apparatus. The bony wall of the tumour was cut away for about four inches and the contents, which were soft, and yellowish in colour, were scooped out with a sharp spoon. The small lower growth seen in the skiagram was left alone. The inner aspect of the hollow was then thoroughly cauterised and swabbed over with pure

carbolic acid, and the great cavity was finally packed tightly with iodoform gauze soaked in turpentine. An antiseptic dressing and a splint were bandaged on and the constricting band was removed. Absolutely no hæmorrhage occurred.



Skiagram of tumour showing loculi formed by thin bony septa.

Dr. H. D. Rolleston, who kindly examined the tumour microscopically, reported that the "growth shows myxomatous tissue, and in places the structure suggests a spindle-celled sarcoma, while in others there are young cartilage cells. It is more probably a myxo-chondroma with recent sarcomatous change than a chondrifying myxosarcoma. There are numerous areas of fatty degeneration in the tumour."

The cavity slowly became obliterated by granulation tissue, and the gauze packing, which was removed daily after soaking the arm for some time previously in a bath of hot boric lotion, was omitted on Oct. 22nd. On Nov. 3rd the patient unfortunately developed a severe sore-throat, and the tonsils and uvula rapidly became covered with a yellowish white exudation, and the glands behind the angle of the jaw were enlarged and tender. The temperature, however, never rose above 99·8°F., and although the exudation was examined several times by Dr. C. Slater, bacteriologist to the hospital, no diphtheria bacilli were ever found. By Nov. 10th the throat was well and the wound in the forearm was practically healed, and she was discharged from the hospital on Nov. 17th. Her present condition is excellent. The swelling is much smaller, the arm is strong and can be used freely, and all pain has disappeared.

Remarks by MR. MARMADUKE SHEILD.—It is too early to say if the cure can be considered permanent. The suspicion of sarcomatous elements being mixed with the cartilage makes one cautious in prognosis. In instances of chondrosarcoma of the bones the growth has repeatedly been known to recur in other parts, as the lungs or the meninges of the brain. The consolidation and shrinkage of the osseous shell, however, look very promising, and time alone can settle the question of local or general recurrence. The skiagram shows a small growth lower down in the shaft. This may possibly take on growth and expand the bone, but if it does so it will be treated in the same way as the larger growth.

This case is an extremely interesting example of what help may be obtained by skiagraphy in the diagnosis of tumours of the bones. Of course, all exostoses appear plainly. Periosteal sarcomata merely give a faint shade unless impregnated with calcareous salts. Cavities in the bone, the site of cysts or abscesses, are usually distinctly demonstrated. In the present illustration the lobulated outline characteristic of cartilaginous tumours is plainly seen. And this, with the long history of the growth, rendered an approximate diagnosis possible.

Enucleation of tumours of bone has long been practised by surgeons, but the true ultimate results are perhaps hardly enough known. Many of the cases are done in hospital practice, and the patients are lost sight of, and the experience gained is lost or lies buried in the private mausoleums of hospital notes. Hitherto the operation has usually been done for myeloid growths, and I have seen it twice performed for these tumours in the head of the tibia. Both cases were very unfavourable. In one the growth rapidly recurred; in the other sepsis supervened and the knee-joint suppurated. The operation has also been done for angiomata of bone—so-called osteo-aneurysm. The differential diagnosis of these growths from very vascular sarcomata is vague and unsatisfactory, and in some reported cases diagnostic errors are manifest.

As regards central enchondromata of bone they are undoubtedly rare. By far the greater number of these tumours originate on the surface of the bones, in which by pressure they may form deep hollows. Fixed by the periosteum and fascia the similarity to a tumour growing out of a bone is very great. I have seen one of the best of the former surgeons in London amputate a finger when he supposed the bone was distended by a cartilaginous tumour, and the growth fell from the bone upon the ground after the periosteum was divided over it. The appearances of the cartilage in the present case, especially the lower patch, are very suggestive of "islets" of undeveloped cartilage left in the bone, though there is no evidence of old marked rickets in the patient.

The case is of importance and interest in showing how far central tumours can be diagnosed by the x rays and as affording an undoubted example of the efficacy of the practice of enucleation in suitable cases. The method of operating, making the part exsanguine and stuffing with turpentine gauze before removing the bandage above, renders it possible to perform such operations with no loss of blood whatever. My previous experience of enucleation of tumours of bone has been confined to the jaws. I have had one instance of enucleation of a myeloma from the antrum of Highmore and one from the lower jaw which seemed permanently cured. At least, there was no return after three years. I have also had one case of large cyst of the lower jaw which contained brownish fluid sparkling with cholesterine. This was opened, scraped out, and stuffed, with a tedious after-treatment, but ultimate cure. I never was able to establish clearly the pathology of this remarkable cyst, but I believe it was quite unconnected with dental causes.

CUMNOCK COTTAGE HOSPITAL, AYRSHIRE, N.B.

A CASE OF ABSENCE OF THE ANUS AND RECTUM, WITH COMMUNICATION BETWEEN THE INTESTINE AND URINARY TRACT; OPERATION WITH RECOVERY.

(Under the care of Dr. JAMES MCQUEEN.)

DR. J. MCQUEEN is to be congratulated on the favourable result of the operation which he performed in the following case, for these abnormal communications between the rectum

and bladder are not prone to close spontaneously, even though a free way be made for the contents of the bowel. He was, however, clearly in the right in endeavouring to establish the normal channel. This should always be done if it be possible to reach the rectum from the perineum, for in these cases it may be found practicable to close the recto-vesical communication at a subsequent operation. Formerly it was advised, as he mentions in his remarks, to make an artificial anus in the inguinal region to divert the fæces, but of late years it has been recognised that the benefits of a normally situated anus outweigh the extra risks of attempting to open the bowel from the perineum and the possibility of non-closure of the recto-vesical fistula.

A married woman was confined at the Cumnock Cottage Hospital on July 23rd, 1900, of a healthy, well-nourished male child. While visiting her on the following day Dr. McQueen's attention was directed by the midwife to the fact that there was "something peculiar" about the anus of the child. On examination it was found that the anus was absent and that at the point where it would have been expected there was a papillary projection closely resembling a small external pile. There was no bulging in the perineum. During the examination of the child a small quantity of fæcal-stained mucus exuded from the urethra. On inquiry it was found that this had occurred on several occasions since birth. After explaining the serious nature of the condition permission was obtained to attempt to remedy it.

The papilliform projection already noted was first removed and the incision was extended towards both the coccyx and the pubes. As there was no appearance of a rectum or any bulging point dissection was carefully carried up, keeping well into the surface of the sacrum. On getting to a depth of about one and a quarter inches a tense shining membrane was met. On inserting the finger it was found that this bulged downwards when the infant cried or strained. With some difficulty the membrane was seized with a bulldog forceps, and on making an exploratory puncture some meconial-stained fluid exuded. The gut was now separated from its connexions, but considering the depth and narrowness of the opening and the proximity of the peritoneum this could not be done to any great extent. The gut having been pulled down to the surface was incised for about half an inch and a large quantity of meconium was evacuated. The lips of the opening into the bowel were stitched to the lips of the cutaneous incision and a dry dressing was applied.

The progress of the case for the next two days was uneventful. On the third day it was found that the stitches had sloughed out of the friable perineal tissues. The gut had retracted a short distance, but the red, pouting mucous membrane formed a guide to the object sought. It was again pulled down and stitched as before, but on the fourth day the stitches again gave way On this occasion, however, the bowel had not retracted so far and consequently it was deemed advisable to leave the structures as they lay. Four weeks later the orifice became constricted and fæcal matter was again passed from the urethra, but not in great quantity. Digital dilatation was performed and continued once a week for three weeks, the mother being instructed to pass a bougie twice daily. The bougie was afterwards alone used, but in 10 days slight constriction again occurred. On inserting the finger a little fæcal matter exuded from the penis, although the mother had not observed any for some weeks previously Since then the case has proceeded in an eminently satisfactory manner. For the last 15 weeks no fæces appeared in the urine and the bougie is now only occasionally used. The only thing that one can note on external examination is that the anus is deeply planted, doubtless owing to the gut dragging on the surface incision. The child's health has all along been excellent, and he is at present (aged five and a half months) a well-nourished, healthy child.

Remarks by Dr. MCQUEEN.—The above case seems to be interesting from two points of view, especially because of the probable etiological explanation of the condition viewed from a developmental standpoint, and the bearing of this on the operative procedure and its result.

1. The bladder and urethral tract develop from the allantois which is an invagination of the wall of the hinder part of the primitive intestine. The neck of the allantois becomes obliterated, but in the case noted this seems to have persisted, maintaining the connexion between the blind pouch of gut and some part of the urinary tract during extra-uterine life. In addition the proctodæum was absent and consequently no rectum was formed to evacuate the contents of the intestine. The fistulous tract which persisted was analogous to a Meckel's diverticulum—the persistent neck of the umbilical vesicle, or to a persistent neurenteric canal communicating with the post-anal gut or to a patent urachus. All of these conditions are found as anomalies in extra-uterine life. In the case under discussion it is impossible to say at which point of the urinary tract the fistulous connexion with the intestine persisted. Judging from the depth at which the gut was found it seems not improbable that the junction was high up, possibly in the lower part of the bladder.

2. If this be the real explanation of such a case is it not possible that the fistulous connexion may close up spontaneously when nature has dispensed with its services through the aid of operation? The neck of the umbilical vesicle, the neurenteric canal, and the urachus are all normally closed when their functions are taken up by other organs. So in a case like the present: free passage has been given to the contents of the intestine and the persistent allantoic neck has probably become obliterated.

Judging from text-books the perineal operation is practically discarded as hopeless in cases like the present; it is recommended that a colotomy be performed at once. An artificial anus in the loin is quite consistent with life, but the discomfort and inconvenience must be very great. Besides, the mortality incidental to this operation in infants is very high. Granted that a vain search be made through a perineal incision in such a case, it can easily be closed up and a colotomy performed. By a colotomy, of course, the fæces are thrown out ere they reach the allantoic neck, and so the danger of their passage into the urinary tract is entirely obviated. In a perineal operation, however, there seems a reasonable hope that the fistula will be closed through its function having been superseded by the relief given by operation, although for a short period a little fæces may pass at times. It may be argued that the smallest quantity entering the bladder is a danger, but there is also the probability that the neck of the allantois will not be wider than the urethra, and that consequently what enters by the one can be thrown out by the other. Obviously, at all events, whatever operative interference is determined upon it must be radically carried out, and that, too, without delay if a favourable termination be anticipated.

Medical Societies.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Epidemic of Arsenical Poisoning in Beer-drinkers in the North of England during the year 1900.

A MEETING of this society was held on Jan. 8th, Dr. F. W. PAVY being in the chair.

Dr. ERNEST S. REYNOLDS (Manchester) made a communication on an Epidemic of Arsenical Poisoning in Beer-drinkers in the North of England during the year 1900 (illustrated by lantern slides). Dr. Reynolds's attention was first drawn to this subject in June, 1899, when he noticed an unusual number of cases of various skin eruptions, amongst them as many as five or six suffering from erythromelalgia in the workhouse infirmary. Later there was an unusual number of cases of peripheral neuritis. He then noticed that the skin eruptions occurred in the patients suffering from neuritis, and remembering that herpes might be produced by arsenic he suspected the beer, which was the apparent cause of the multiple neuritis in these patients. Professor Sheridan Delépine analysed various specimens of beer and found that they contained quantities of arsenic varying from two to four parts per million, which was equivalent to about one grain of arsenious oxide in three gallons. The same observer had found that invert sugar might contain 0·2 parts per 1000, glucose 0·8 parts per 1000, and sulphuric acid as much as 1·4 per cent. of arsenious acid, which was equivalent to four ounces of arsenious acid in the gallon, all of which substances were used in the manufacture of beer. Traces of arsenic could also be found in "sulphured" hops, various malts (from the anthracite used in manufacture), and in the vulcanite tubing. Various observations had led to the discovery that many beers were extensively contaminated with arsenic and that the beer and stout in

London contained a good deal of arsenic. The epidemic under investigation had occurred chiefly in the north of England and to some extent in the midland counties. Many thousands of persons had been affected. It was not possible to get accurate figures, but Dr. J. Niven, the medical officer of health of Manchester, had estimated that at least 2000 persons in Manchester had suffered from arsenical poisoning. The patients complained of a variety of symptoms, such as pain in the feet and limbs, pins-and-needles, tingling in the soles of the feet, general weakness, difficulty of walking, swollen feet, and vomiting and diarrhœa. The aspect presented by the patients was so typical that a diagnosis could be made at sight by those accustomed to see these cases. There was a puffiness, especially about the eyelids, and a deep crimson colour of the face. The walk was also very characteristic—it was as though the patient's feet were sore; later there was the high-stepping gait. Numerous skin eruptions appeared—erythromelalgia was perhaps the commonest. It consisted of a painful red swelling of the hands and feet. This erythematous condition was most intense along the edges, the centre of the palms being almost exempt. The pain was very marked, so that the patients could not sleep. These red patches were followed by keratosis of the hands and feet, the scales being exfoliated so plentifully that a two-ounce bottle could be filled with the flakes in a short time. This symptom (keratosis) was very important in the diagnosis because fair-haired persons did not get pigmentation. If a fair-haired person was affected with such keratosis, accompanied by well-marked peripheral neuritis, there was a strong presumption of arsenical poisoning. There were also scarlatiniform and morbiliform erythematous rashes. The first of these started like scarlet fever with a collaret round the neck. Sometimes there were papular eruptions and sometimes vesicular and bullous eruptions. These rashes might come on as late as six weeks after ceasing to drink the beer. Pigmentation was very common and a study of these cases showed that the older descriptions were not quite correct. It was true that some of the cases presented clear, isolated spaces of normal skin situated in a generalised pigmentation, but this was not always the case. 21 cases had presented herpes in various situations. A study of these had led Dr. Reynolds to the conclusion that herpes could be caused by the direct action of arsenic on the posterior spinal ganglion, and he could not agree with Dr. Henry Head's conclusions on this subject. Sometimes the eruption was preceded by severe neuralgic pains. The nervous systems of these patients had been very extensively affected and their symptoms corresponded in most particulars with what was known as alcoholic paralysis. The intense tenderness of the muscles was very characteristic. There was anæsthesia, but this was rarely complete. The mental condition was peculiar, this being characterised by loss of memory for time and place and a loss of power to initiate ideas; the latter features were wanting in many of the epidemic cases. The arsenical poisoning was seen to affect the heart muscle very seriously. The heart became dilated and there might be œdema of the feet and the chest wall. Death usually ensued from some form of cardiac failure. Dr. Reynolds's cases had presented the same generalised catarrh of the mucous membrane which Brouardel had observed in 1888 in an epidemic affecting 15 persons where arsenic was given for homicidal purposes. *Apropos* of the administration of arsenic in cases of phthisis he (Dr. Reynolds) had noticed that when patients who were the subjects of phthisis had taken the arsenical beer, instead of improving them they had rapidly gone to the bad. Vomiting had been a very constant feature in his cases, affecting as many as 75 per cent., and so also was diarrhœa. The urine of many of the patients had contained arsenic, which could be found as long as two weeks after ceasing to take the contaminated beer. Arsenic was also secreted by the milk. In some of the cases the temperature had been elevated. A study of his cases had led him to the conclusion that arsenic was a cumulative poison and was not eliminated at once. It appeared to affect the skin, the respiratory and digestive mucous membranes, the nervous system, the heart, and the liver. As regards varieties there were four groups: one in which the patients presented *all* the symptoms previously mentioned, a second in which the skin lesions predominated, a third in which the cardiac and other visceral lesions were the most pronounced, and a fourth in which the paralytic symptoms predominated. The disease might last for from 18 months to two years, though some patients got well in a few weeks. There had never been any difficulty about the diagnosis, though similar cases at Chester had been diagnosed as beri-beri by a physician who had practised in the tropics. In beri-beri, however, there were no skin lesions such as these patients presented. Dr. Reynolds then referred to some previous epidemics of arsenical poisoning. In one which was recorded by Chomel in 1828 and was known as the "épidemié de Paris" 40,000 persons had died in seven months. Graves's description of the clinical phenomena in this epidemic exactly tallied with those at Manchester. There had been an epidemic at Havre in 1888 which had affected 15 persons and which had been described by Brouardel and Pouchet. In the same year 480 persons had been attacked at Hyères by arsenic contained in wine, a record of which had been made by Barthelmy. In 1880 there was an epidemic at St. Denis in which 218 persons had been poisoned by arsenical bread. Returning to the Manchester epidemic Dr. Reynolds said that he had had 500 cases under his care; 291 of the patients were males and 209 were females. He was, however, under the impression that more females had been attacked, though they did not so readily come forward for minor complaints, probably from reasons of modesty. As regards the several lesions, herpes, heart affections, and hepatic symptoms had been more common among the men, but all the other symptoms were more marked among the females.

A communication from Sir W. R. GOWERS was read by the SECRETARY in which he drew attention to the remarkable immunity from arsenical poisoning experienced by those patients who took that remedy combined with bromide for a very long time. He had had a very large number of cases of epilepsy in which a proportion of 10 minims of liquor arsenicalis to 60 grains of bromide had been administered for long periods of time, but he only remembered to have seen one case of chronic arsenical poisoning among them. He suggested that alcohol in conjunction with the arsenic was a very potent poison for the production of peripheral neuritis. He narrated several cases in illustration of his statements.

Dr. BUZZARD complimented Dr. Reynolds on his communication. There was no doubt that these cases were examples of multiple peripheral neuritis. Moreover, there seemed no doubt that this was in very large part due to the effects of arsenic, though he could not regard this reagent as the sole cause. Dr. Reynolds had seemed to suggest that all cases of what they now regarded as alcoholic neuritis were in reality a form of arsenical poisoning due to the imbibition of beer. But he could not subscribe to such a theory, for he had seen many cases which had been produced by brandy and wine, and his opinion was that the drinking of crude spirits alone was quite capable of producing peripheral neuritis. This, indeed, was the original doctrine. Later the disease had been traced to beer. Turning to the symptoms of arsenical neuritis, acute tenderness of the muscles was an equally prominent symptom in alcoholic neuritis. Keratosis, he thought, might also be met with in alcoholic cases, and he had seen considerable disturbance of the cuticle on the soles. He would like to ask if the epidemic had occurred in persons who were only moderate drinkers of beer. The relative absence of mental symptoms in Dr. Reynolds's cases confirmed the idea that they were due to arsenic rather than to alcohol. Like Sir William Gowers, he (Dr. Buzzard) could not help drawing a comparison between the arsenical poisoning of beer-drinkers and the absence of symptoms in epileptic and other patients who took far larger quantities of arsenic for longer periods of time. Reference was made to an investigation which had been made into 17 specimens of beer in which arsenic had been found in proportions varying from a mere trace to 0·28 parts per gallon, representing an average, say, of $\frac{11}{100}$ths, or about one-ninth, of a grain of arsenic per gallon of beer. A patient would thus take a quantity of arsenic equivalent to about two-thirds of a minim of Fowler's solution to a glass, and a moderate drinker would only take a tithe of the quantity of arsenic which an epileptic would be taking. What was the cause of this apparent inconsistency? There was no doubt a liability in some persons to suffer from arsenical poisoning, and Dr. Buzzard referred to the case of a man, aged 55 years, who after taking rather less than 15 grains of arsenic in the form of Fowler's solution in the course of seven weeks presented erythematous swelling and exfoliation of the palms of the hands and the soles of the feet, peeling of the skin, loss of

knee-jerks, and diminution and perversion of sensation. He ultimately made a good recovery.

The discussion was adjourned.

OBSTETRICAL SOCIETY OF LONDON.

Primary Ovarian Pregnancy with Rupture 14 Days after last Menstruation.—Exhibition of Specimens.

A MEETING of this society was held on Jan. 2nd, Mr. ALBAN DORAN, the President, being in the chair.

Mr. G. P. ANNING and Mr. HARRY LITTLEWOOD communicated a paper on a case of Primary Ovarian Pregnancy with Rupture 14 days after last Menstruation. The patient was aged 28 years and had been married five months; there had been no previous pregnancy. Menstruation was usually normal. She was operated upon on August 27th, 1900, for a ruptured ectopic gestation, about 36 hours after the rupture. About two pints of blood and clots were removed and a small ovum of about the size of a Barcelona nut was found. This fitted into a firm envelope composed of laminated clot. There was a rent in the right ovary leading to a cavity which contained some blood; into this the ovum and its sac exactly fitted, clearly indicating the primary ovarian origin of the pregnancy. The right tube was removed and showed no evidence of rupture. The left tube was examined and was found to be normal. The cystic portion of the left ovary was removed. The patient made a good recovery. The specimens were shown, with microscopical sections of the ovum, the sac, and a portion of the ovarian wall.

Mr. BLAND-SUTTON remarked that belief in ovarian pregnancy could be traced back more than two centuries, but a critical examination of recorded cases showed that in some instances the supposed ovarian fœtus was in reality a dermoid and in others a sequestered fœtus (lithopædion) in the broad ligament. In a few instances the account of the dissection was so careful and circumstantial as to leave the impression that the formation of the embryo in the ovary could not be denied. It must also be borne in mind that the modern cases prior to 1899 rested upon no safer evidence than the non-detection of the ovary during an operation or upon the post-mortem examination of a person with an advanced extra-uterine gestation. Even such a careful and judicious writer as Dr. Farre did not deny the possibility of a spermatozoon entering an ovarian follicle, but he denied that any case of ovarian gestation had been satisfactorily proved. Mr. Bland-Sutton came to the same conclusion after a study of a much larger number of specimens than were available to Dr. Farre and with the advantage of modern methods of histological research. His (Mr. Bland-Sutton's) investigations had been particularly directed to the very early stages, for he urged as a postulate that if the ovum was really capable of being fertilised in its follicle "an early embryo in its membranes contained in a sac in the ovary" should be forthcoming. He was convinced that the specimen now before the society was an example of early ovarian pregnancy; the only possible objection that could be raised to this view of its nature depended on the fact that Mr. Anning and Mr. Littlewood had not taken any steps to prove that the "mole" had not been ejected through the cœlomic ostium of the tube (tubal abortion). Mr. Bland-Sutton would not press this objection because he had sections of a more complete specimen which quite satisfied him that an ovum could be fertilised whilst in its follicle. Mr. Anning and Mr. Littlewood were entitled to, and would receive, the best thanks of the Obstetrical Society for their kindness and energy in coming from Leeds and recording a case that would become historic. Since the last meeting of the society Mr. Bland-Sutton had visited Amsterdam, and through the courtesy of Dr. Catherine van Tussenbroek had been able to see the early example of ovarian pregnancy described by her and had brought back sections which would be available for inspection by any Fellow of the society. There were a few features particularly worthy of mention in connexion with this important case. The condition of the parts was exactly analogous to that of a tubal mole, so that for convenience of reference they would have to speak of it as an "ovarian mole"; the blood corpuscles in the vessels of the villi were nucleated; there was no trace of a decidua in the ovarian follicle; and it was an interesting fact that in the clinical report of the case it was stated that a decidua had formed in the uterus, and a few days after the operation was discharged with the *douleurs d'accouchement*. Mr. Bland-Sutton further stated that he had always been candid in his expressions of doubt regarding the older cases of alleged ovarian pregnancy inasmuch as they could not be again brought under observation and re-examination in the light of new knowledge; hence his persistent request that the postulate in regard to the presence of an early embryo in a sac inside the ovary should be satisfied. Another matter profoundly interesting to him was the fact that the "mole" with its chorionic villi which had become the criterion for many cases of early tubal pregnancy seemed likely, from this specimen, to become the criterion of early ovarian pregnancy also, and a large field of inquiry had thus been opened, for the condition known as blood cysts of the ovary would now require very careful investigation in the new light afforded by this remarkable and epoch-making specimen.

Dr. A. L. GALABIN thought that the society might be congratulated that this much-controverted question might now be considered finally settled since Mr. Bland-Sutton was converted. He had always believed in the possibility of both ovarian and primary abdominal pregnancy and thought that those who denied it had gone upon an *a priori* assumption that the tube was the only structure besides the uterus which could give primary attachment to the ovum. He had not himself met with a case of ovarian pregnancy but believed that he had met with one of primary abdominal pregnancy which was presented to that society and reported on by a committee as being probably of that nature.

After some remarks by Dr. W. S. A. GRIFFITH and Dr. ROBERT WISE,

Mr. LITTLEWOOD said he thought that the case clearly proved the possibility of a primary ovarian pregnancy and was glad to have had the opportunity of bringing the specimens to the first meeting of the Obstetrical Society in the new century. He thought that the society was greatly indebted to Mr. Bland-Sutton for having gone to Amsterdam and for bringing the specimens which he had shown.

The PRESIDENT referred to his own analysis of cases of alleged primary ovarian pregnancy published in the thirty-fifth volume of the society's Transactions. In both Sänger's and Leopold's specimens there was a lithopædion, and, as might be expected, the relation of the sac to the Fallopian tube could no longer be accurately determined. In Herzfeld's and many other cases the fact of the tube being intact was erroneously taken for proof that the pregnancy could not have begun in its canal. But Patenko's case seemed more probably genuine. In Dr. Croft's case the evidence was strong, but the pregnancy was somewhat advanced. Mr. Bland-Sutton deserved credit for the trouble which he had taken to make sure about van Tussenbroek's case, which seemed to offer almost conclusive evidence of primary ovarian pregnancy. The same might be said of Mr. ANNING's and Mr. Littlewood's case. The President suspected that these primary ovarian pregnancies aborted and broke down early, as seen in Patenko's specimen. Late ectopic gestations could generally be explained as developments, more or less evident, from a tubal sac.

Mr. ANNING replied

The following specimens were exhibited:—

Dr. G. E. HERMAN: Sarcoma of the Stomach.

Dr. HERBERT SPENCER: Large Uterus with Cervical Fibroid removed by abdominal hysterectomy by Doyen's method.

Dr. CUTHBERT LOCKYER: Congenital Omental Hydrocele.

Dr. WILLIAM DUNCAN: Gravid Uterus removed at Full Term by Intra-peritoneal Hysterectomy in a case of Contracted Pelvis.

The PRESIDENT: Acute Torsion of Ovarian Pedicle.

The specimens were discussed by the above and by Dr. GALABIN, Dr. GRIFFITH, and Dr. AMAND ROUTH.

HARVEIAN SOCIETY OF LONDON.

Exhibition of Cases.

A MEETING of this society was held on Jan. 3rd, Dr. W. H. LAMB the President, being in the chair.

Dr. LEONARD GUTHRIE showed a woman, aged 58 years, who had first come under observation two years previously. She then complained of palpitation, dyspnœa, tremblings, flushings, profuse perspiration, vague aches and pains, constipation, and general debility. The catamenia had ceased for two years. She had noticed swelling of her throat for

four months, and on examination the thyroid gland was found to be considerably enlarged. There was no proptosis, but the heart was irregular and intermittent and the pulse-rate was persistently from 120 to 130. She had also fine tremors characteristic of Graves's disease. There were no signs of myxœdema, but thyroid extract in five-grain doses was given tentatively at night only. She professed to feel great relief from this treatment and the goitre gradually dwindled until, in October, 1899, it was barely perceptible. She continued to take a five-grain tabloid of thyroid extract every night until June, 1900, when she was confined to the house by an abscess in her foot and the treatment was discontinued. On returning to hospital in December, 1900, she presented all the signs and symptoms of advanced myxœdema. She had grown very bulky and was so weak that she could hardly walk. Her skin was coarse and quite dry, her complexion was yellow, her cheeks were flushed, her eyelids were bluish and baggy, her hair and eyebrows were falling off, and her speech was thick, indistinct, and slow. The thyroid gland could not be felt, but there were two large soft symmetrical swellings above each clavicle which she had noticed for a month. After a fortnight's treatment by thyroid extract the symptoms and signs of myxœdema had almost subsided, but the pulse was rapid as it had been at first. Only a few cases of myxœdema following Graves's disease had been recorded, but Dr. Guthrie thought that the sequence was not uncommon.—Dr. JAMES TAYLOR discussed the case.

Mr. JACKSON CLARKE showed a man, aged 30 years, one of whose feet he had removed three months ago for a severe injury. The patient's left leg had been caught in the wheel of a tramcar and there was severe contusion of the soft parts nearly to the level of the tibial tuberosity. There was a deep wound below the internal malleolus; the posterior tibial vessels were torn through. The tissues of the sole of the foot were much contused. If primary amputation had been done in this case the limb would have been removed in the upper part of the leg; by waiting it had become possible to do a more conservative operation. When in the presence of severe injuries it was decided to wait every care must be taken to prevent sepsis.—Mr. RAYMOND JOHNSON was strongly in favour of avoiding primary amputation in many severe injuries of the hand and foot, for in many instances the extent to which the parts lost their vitality was much less than was at first expected and thus a formal amputation became unnecessary.

Dr. RISIEN RUSSELL showed a case of Myopathy with marked fibrillary tremors of the muscles in a male, aged 19 years. No other members of the family were similarly affected. The patient had enjoyed good health before the onset of the present illness but had suffered from weakness of the legs five years ago. This weakness had steadily progressed, but much more rapidly since a year ago when the arms first commenced to be weak. Fibrillary tremors were noticed seven months ago. The face was not affected and the muscles of the neck were intact. The lower part of the trapezius was not so well preserved as was the upper part and there was marked wasting of the following muscles: the infra-spinatus, the latissimus dorsi, and the triceps, biceps, and supinator longus. The trunk muscles were weak, as were the extensors and flexors of the hip, the extensors of the knee, and to a slight degree the calf muscles. There was marked atrophy of the glutei and of the quadriceps extensor; the sartorius and the adductors were also wasted and the calves were small. The muscles were symmetrically affected, none of them were enlarged or unduly firm, and those which were atrophied showed diminished excitability to both forms of electrical currents, without evidence of the reaction of degeneration. The fibrillary tremors were very pronounced and were not limited to the atrophied muscles. The triceps-jerks and knee-jerks were absent, the plantar reflex was normal, the sphincters were intact, and there was no blunting of cutaneous sensibility.

Dr. JAMES TAYLOR showed two cases of Syringomyelia. In one case, that of a female, aged 21 years, there were wasting of the small muscles of the right hand and the characteristic claw-like deformity. There was distinct anæsthesia, especially for thermal and painful stimuli, as high as the elbow on that side. There were nystagmus and lateral curvature of the spine but no affection of the face or lower limbs. Her symptoms had commenced about two years ago. The second case was that of a man with paralysis of the sixth, seventh, and twelfth cranial nerves on the right side, anæsthesia of the right side of the face, the right arm and the right side of the trunk, and some muscular wasting especially about the shoulders. There was also a spinal curvature but no affection of the legs. His condition had not appreciably altered in the last six years.—Mr. JACKSON CLARKE asked whether in these cases the spinal curves were of the same character as were those seen in some cases of infantile paralysis—i.e., whether the convexity of each curve was directed to the section of the spinal muscles that were the more extensively paralysed.—Mr. RAYMOND JOHNSON inquired as to the period of the disease at which the scoliosis was likely to develop, and if it ever occurred as the first symptom and that for which the patient alone sought advice.

Dr. HERBERT TILLEY showed a woman, aged 46 years, upon whom he had performed Kundt's Radical Operation for Chronic Empyema of the Left Frontal Sinus. The operation consisted of complete removal of the anterior bony wall of the sinus, curettage of the degenerated mucous membrane lining the cavity, and the application of the anterior soft parts to the posterior bony wall of the sinus. Some of the main features of the operation were briefly dwelt upon and it was pointed out that although the result as regards the cure of the disease was so excellent, yet it was purchased at the price of more deformity than resulted when less of the anterior wall was removed. The latter result had been demonstrated by cases hitherto shown at the society's meetings. The symptoms of which the patient had complained were chronic and severe left frontal headache, discharge of pus from the nose, and nasal obstruction due to polypi. These had completely disappeared since the operation. The patient was in the hospital for 17 days.

Mr. E. W. ROUGHTON showed a man, aged 35 years, with a Lump in the Dorsum of the Tongue. Although it resembled malignant disease he regarded it as a case of syphilitic induration.—Mr. RAYMOND JOHNSON thought that the lump in the tongue, although not malignant, should be excised if it did not subside under anti-syphilitic treatment.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF PATHOLOGY.

Bacillus Aerogenes Capsulatus.—Exophthalmic Goitre.—Segmentation of Heart Muscle.—Intra-ocular Sarcoma.—Tuberculosis of the Conjunctiva.

A MEETING of this section was held on Nov. 30th, 1900, Dr. A. C. O'SULLIVAN, the President, being in the chair.

Professor E. J. MCWEENEY gave an account of some work which he had lately done on Bacillus Aerogenes Capsulatus. A man whose arm had been ground almost to a pulp by a threshing machine was admitted into the Mater Misericordiæ Hospital and did not long survive amputation. At the operation a peculiar gelatinous state of the tissues was noted. The day following death the body presented a remarkable appearance, being swollen to twice its size, covered with huge bullæ, nearly black in colour, and crepitant wherever touched. The skin was so softened that a blunt pair of forceps could be thrust through with perfect ease, and from the apertures so made a frothy fluid, made up of turbid serum and sour-smelling gas, issued forth. The microscope revealed large anthrax-like bacilli in enormous numbers, mingled near the operation wound with smaller forms. By means of anaerobic plate cultures, made over alkaline pyrogallol in a special dish [exhibited], isolation of the large bacillus was accomplished, though not without difficulty. It was associated with bacillus coli and a streptococcus, both of which grew quite well in the total absence of free oxygen. The gas-forming bacillus was quite as large as that of anthrax, stained well by Gram's method, was non-motile, devoid of spores, and possessed a thick capsule which usually remained unstained. It appeared to grow most luxuriantly in 1 per cent. of sodium-sulphindigotate-agar, the medium becoming decolourised, save the upper centimetre where the oxygen necessary for the pigmentation was supplied by the atmosphere. It also grew well on ordinary media in an atmosphere of hydrogen, but not in coal-gas. Rabbits killed shortly after intravenous injection with half a cubic centimetre of fluid containing bacilli in suspension became distended with gas. The heart and vessels

contained frothy blood, and the liver was converted into a soft, dark grey mass, riddled with cavities containing gas. [A specimen of such a liver—the "Schaumleber" of German post-mortem rooms—was exhibited.] A rabbit which had been injected intra-muscularly with the pure culture suffered from a spreading gangrenous process, but this was found at the necropsy to be due to a mixed infection. Professor McWeeney demonstrated a preparation from the gangrenous tissue of the rabbit, showing the large gas-bacilli stained by Gram's method, while the symbiotic intrusive organism was counter-stained red with fuchsin. Contact preparations from anaerobic plate cultures showed a marked tendency of the bacilli to form angles like a capital V. Although the condition in the present case only came on post mortem, the bacillus had been proved by Welch, Flexner, and Nuttall to cause a spreading emphysematous gangrene in the living subject, and had also been found in various other conditions associated with development of gas during life or immediately after death.—Dr. KNOTT asked what was the relationship between this organism and that of anthrax in cases of quarter evil, or, as it was called in Ireland, "black-quarter," which occurred in young cattle.—Professor MCWEENEY, in replying, said that the bacillus coli produced gas in sugar media with just the same amount of vigour as the large bacillus of emphysematous gangrene. The bacillus to which Dr. Knott had alluded as being present in animals, was the bacillus of symptomatic anthrax, or Rauschbrand, known to the French as Chauveau's bacillus. It was an anaerobe closely allied to the one which he had shown, but differing from it in forming spores, in being motile, and in not being capsulated.

Dr. O'CARROLL read notes of a case of Exophthalmic Goitre in a girl, about 20 years of age. Post mortem the thyroid gland, which had been hardly at all enlarged in the neck, was seen to be greatly enlarged within the thorax, where it almost impinged against the arch of the aorta and probably did actually impinge upon it when both structures were distended with blood during life. The case was further noticeable, inasmuch as the thymus was so large as to reach down to the front of the pericardium, and it presented the structure of that organ found in infancy.

Dr. H. C. EARL showed a microscopical section of the Heart of a Woman who had died from poisoning by phosphorus. The section showed marked segmentation of the muscle fibre with great separation of the segments. There was no fatty degeneration of the muscles.

Mr. ARTHUR BENSON exhibited specimens of Choroidal Sarcomata mounted in glycerine jelly. One tumour had been removed from a man, aged 62 years, and was a pigmented sarcoma of the choroid. The second specimen was one of non-pigmented sarcoma of the choroid—a much rarer form of tumour than the pigmented. It occurred in a man aged 49 years.

Mr. J. B. STORY showed a case of Tuberculosis of the Conjunctiva, the patient being a boy, aged 15 years. A swelling of the lower eyelid had existed for two months. On everting the lid a small vascular tumour was found springing from the fornix. It looked uncommonly like a cock's comb and was of about the size of a filbert.

HUNTERIAN SOCIETY.—A pathological evening of this society was held on Nov. 28th, 1900, Mr. Dundas Grant, the President, being in the chair.—Dr. Glover Lyon showed a specimen of Total Atrophy of one Kidney and extreme atrophy of the other. The specimen was taken from a boy, aged 16 years, but apparently not older than 10 years, who until a few months before death had been able to follow his occupation of tin-worker. For a few months before admission he had suffered from drowsiness, headache, and diarrhœa. On admission he showed somewhat indefinite symptoms of contracted granular kidney, but there was no œdema present. Death had been due to coma. The interest of the case consisted in the fact that the patient had been able to live comfortably up to the age of 16 years when at death there was certainly not more than one-twentieth of the normal kidney substance available. The pelvis of the left kidney was greatly dilated with a small amount of fibrotic renal tissue superficial to it less than a quarter of an inch in thickness and about three-quarters of an inch long. The ureter was not dilated, but there was no opening of it into the badder. The right kidney was greatly diminished in size. There was great dilatation of the pelvis and the thickness of the renal substance was only from half to three-quarters of an inch. The distinction between the cortex and medulla was with difficulty made out, but the cortex seemed to be relatively very thin.—Dr. F. J. Smith showed the Lungs and Liver of a man, aged 48 years, who had died in the London Hospital. On admission his lungs showed very few physical signs of disease, a little prolonged expiration and an occasional click but nothing else; the sputum, however, showed numerous tubercle bacilli; the liver was much enlarged, it could be felt below the umbilicus and presented many hard nodules; it was not tender. The man was very much emaciated. The diagnosis made was carcinoma of the liver which was considered to be in itself sufficient to account for all the symptoms, though the bacilli in the sputum gave indications of phthisis. The man was very ill on admission and rapidly sank. The post-mortem examination showed that the upper half of each lung was riddled with tuberculous cavities and collections of tuberculous nodules; the liver was stuffed full of nodular masses of a carcinoma the appearance of which suggested that they were secondary, and further search revealed a carcinomatous ulcer of the œsophagus about two and a half inches long, the lower end of which was about three inches from the cardiac opening of the stomach; the ulcer had perforated the œsophagus and would have caused an abscess round the œsophagus had the patient lived.—Dr. Smith also showed the Stomach of a Woman, aged 24 years, the history of whom was that five years ago she had had an attack of severe "indigestion." From this she had never completely recovered, and two years ago she brought up about a teacupful of blood. From that time she had never been able to take any food without great pain. Every form of medical treatment had been tried in vain and finally Dr. Smith, on a diagnosis of chronic gastric ulcer, had taken her in to see what surgery could do for her relief. Mr. Mansell Moullin had opened the abdomen, and finding the stomach quite normal to the touch he had not proceeded further but merely closed the wound again. For five days she had done remarkably well but on the sixth day she was suddenly taken ill with collapse and extremely slow respiration, rapidly followed by death. At the necropsy absolutely nothing was found by the naked eye to account for death; the brain was carefully cut up, but showed no naked-eye changes; the heart, lungs, and kidneys seemed absolutely healthy. The stomach contained two or three large clots of milk, but as the patient had no pain before death Dr. Smith thought that overloading of the stomach was a very doubtful element; in fact, he was absolutely unable to account for death. The inside of the stomach showed an old radiating scar of ulcers on the upper posterior wall about three inches from the pylorus, a sufficient cause of the dyspeptic symptoms during life. Dr. Smith remarked that the case added one more difficulty to the numerous ones surrounding the treatment of alleged gastric ulcers, for in face of the symptoms and post-mortem appearances he did not know any means by which the likelihood of relief from surgery could be ascertained previous to exploration, and the fact of death, coupled with the entire absence of apparent causation, showed that there were still unexplained dangers in abdominal surgery. At the same time, considering the severity of the symptoms he was still of opinion that the right course had been pursued.—Dr. Smith also showed a Heart and Pericardium showing the effects of Adherent Pericardium. The specimen was taken from a man, aged 21 years, who had his first attack of rheumatism at the age of 20½ years. His history presented no points of special interest, the symptoms being those of valvular incompetence and cardiac failure. The necropsy showed the pericardium to be very adherent to the chest wall and universally so to the ventricular surface of the heart, so that the pericardial sac as such was entirely obliterated. The heart weighed 32½ ounces. Dr. Smith thought that such a degree of hypertrophy could not have been reached in five years if it were due to the valvular mischief only. He thought the specimen showed very well the remote dangers of rheumatic pericarditis.—Dr. David Ross showed a case of Congenital Obliteration of the Bile-ducts. The patient was the youngest of three children of healthy parents with no history of syphilis and was brought to Dr. Ross when six weeks old suffering from jaundice which had existed from birth. When born the child appeared normal and well nourished and continued to thrive for about a couple of months when she began to get gradually emaciated. The navel discharged for a month

before finally healing. The jaundice was very marked; the motions had been devoid of colour from the very first, and the urine was very deeply bile-stained. At two months the characteristic subcutaneous hæmorrhages began to appear at various parts, together with occasional melæna. On the right side the liver dulness extended almost to the level of the umbilicus and on the left to about an inch below the costal margin. When 73 days old the child died. At the necropsy the gall-bladder was found to be non-existent, being represented by a few fibrous shreds. The duodenal papilla was well formed, but a bristle passed only into the pancreatic duct and not into the common bile-duct. Microscopically it was seen that the change was due to a small-celled infiltration confined to the interlobular spaces rather than to the presence of much fibrous tissue between the cells. There was no new formation and no great distension of the bile-ducts.—Dr. W. H. Kelson, Dr. J. H. Bryant, Dr. Williams, Mr. J. H. Targett, Mr. Hope Grant, Dr. T. G. Stevens, and the President discussed the cases.

FORFARSHIRE MEDICAL ASSOCIATION. — An ordinary meeting of this association was held in the University College, Dundee, on Dec. 13th, 1900, Mr. C. S. Young, Vice-President, being in the chair.—Dr. Mackie Whyte read a paper on Recent Researches on Alcohol and their Effect on Treatment. He adhered to the views of Schmiedeberg in regarding alcohol not as a stimulant of functional activity but as a paralysing agent. This action on the brain and on muscle was gone over at some length, reference being made to the work of Kraepelin, Destrée, and others. There was no proof of a stimulating effect on the heart. Binz's experiments on the effect of alcohol on respiration were discussed. The effect of alcohol on the tissues was shown in various ways to be deleterious, the proof that it was a protoplasmic poison being considered to be fairly complete. While alcohol taken in moderate amount was to a great extent oxidised its food value must be largely discounted by its other effects. Their knowledge of metabolism was very far from being complete; what they wanted to know in regard to alcohol was what it did before it was transformed into water and carbonic acid. The bearing of these views on the treatment of various classes of disease was next described. The action of alcohol on acute febrile and infectious disorders was gone into at some length, pneumonia being taken as a convenient type.—The Chairman, in the discussion which followed, pointed out the interest such a paper had and referred to the effect of alcohol on the circulation and stated that it was his practice to use alcohol chiefly in tiding over a crisis.—Dr. J. W. Miller said that he agreed in almost everything with the paper. In his own practice he had been steadily diminishing the quantity of alcohol prescribed for patients, especially in acute cases, such as pneumonia and fevers. In pneumonia he never used alcohol largely and was of opinion that it should be used only in the strictest moderation. Dr. Whyte had referred to the danger of discontinuing alcohol suddenly in those cases where its bad effects were beginning to show themselves, but in 28 years' experience of prison practice in which alcohol was at once stopped on admission he had not found such a large number of cases of delirium tremens as one would expect if the practice referred to were dangerous.—Dr. R. Sinclair in his own practice adopted pretty much the same plan as Dr. Miller. In pneumonia the balance of evidence was entirely in favour of the withholding of alcohol until the crisis, and in the majority of cases even then many cases might do better without than with it. He was perfectly convinced of the absolute harmlessness of omitting alcohol altogether in the case of the majority of healthy individuals. In regard to the phthisical cases he entirely agreed with Dr. Whyte; phthisical patients who had been intemperate generally went downhill very rapidly, but with all deference he thought that there was another side to the question. It was, he said, very well known that if a patient with a tendency to phthisis developed the gouty habit it was very hostile to tuberculosis. In the case of young children with a tendency to waste and to take catarrhs readily a little alcohol disguised with bitter infusion so that it should be disagreeable was of distinct advantage in promoting digestion and assimilation. Obstinate neuralgias common in the aged were treated with advantage not only *with quinine* but with a modicum of alcohol along with it. He also thought that ether from the laboratory was not the same as volatile ethers in wines after fermentation and in bottle.—Professor C. R. Marshall agreed that alcohol was a protoplasmic poison and consequently practically toxic to all forms of tissue activity. It was not a stimulant to the brain and there was no scientific evidence to show that the heart was stimulated by alcohol; if it did have any effect it was an indirect one through the stomach. He did not think that Dr. Whyte had laid sufficient stress upon its local effects upon the alimentary mucous membrane. He thought that alcohol had a beneficent effect upon the digestion and did assist the assimilation of food. Alcohol was also a food sparer. It could replace to a certain extent some of the carbohydrate of the food. It was absorbed readily and was easily broken up in the system, but its power in this direction was limited. On the whole he thought that alcohol ought to be regarded as a drug and not as a food or poison except in a limited sense.—Professor A. M. Stalker considered that there was no shadow of proof that alcohol was a cardiac stimulant. He would be inclined under any circumstances to give a patient suffering from pneumonia the chance of recovering without alcohol. As a hypnotic he would use it in certain circumstances and considered it the safest with children.—Dr. G. A. Pirie considered that until physiology could speak with a more certain voice treatment of disease by alcohol must rest on a very insecure foundation, and indeed was dependent mostly upon clinical observation, which was steadily limiting the amount prescribed in many diseases and abolishing it altogether in some.—Dr. Whyte, in reply, stated that the extreme physiological dose was put down as two and a half ounces of alcohol, and that there was now a tendency to diminish and bring this down to about one ounce as the amount which a man could safely from day to day indulge in without producing degenerations. The fact of alcohol being a food-sparer was of very little importance. What they wanted to know was what were the other effects of alcohol; if it was burned up in the body, was it or was it not, as Schäfer said, a deleterious drug? He held that it was.—Professor Marshall said that he assumed it was a protoplasmic poison; that seemed to him to do away with its food value.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—An ordinary meeting of this society was held on Jan. 4th, Dr. F. F. Schacht, the President, being in the chair.—Several new members were balloted for and elected.—The Secretary read a letter from Mrs. Symons Eccles thanking the society for its letter of sympathy on the death of her husband, Dr. A. Symons Eccles, a Vice-President of the society.—Mr. J. Jackson Clarke read a paper on Some Surgical Phases of Rheumatoid Arthritis and Similar Affections. The conditions dealt with were chiefly deformities and included spinal curvature, various joint contractions such as hammer-toe and flat-foot, talipes equino varus with pes cavus from gouty or rheumatoid myositis, Dupuytren's contraction, and deformities due to paralysis from peripheral neuritis. Mr. Clarke dealt on the need of the coöperation of the physician and surgeon in the management of these conditions. In many of the cases instruments were of the utmost value in treatment. He thought that the surgeon should be able to prescribe instruments with as much completeness as the physician prescribed medicines. Cases and photographs illustrating the paper were shown.—The President thanked Mr. Jackson Clarke for a very interesting paper.—Mr. C. R. B. Keetley thought the subject almost too wide a one for an evening's discussion, more especially as it was hardly understood what was meant by rheumatoid arthritis. He thought it was generally understood to be some infection of the blood which tended to influence lining membranes of joints and their vascular tissues and which produced pain and inflammation but did not go on to suppuration; at the same time it profoundly altered the nutrition of the joint and surrounding tissues. It was generally taught that gout was the cause of Dupuytren's contraction, but he had had cases lately which had a clear rheumatic history. He thought that some cases of syphilitic or gonorrhœal infection were sometimes diagnosed as rheumatoid arthritis. Bad cases of flat-foot he often treated by Ogston's operation and he obtained a very good result thereby. In one extreme case he had excised the astragalus with benefit. He thought that severe cases might also be treated by excision of the tibia above the ankle-joint, but preferred Ogston's operation.—Dr. F. H. Alderson said he did not think that hammer-toe was always the result of rheumatism and he had had cases with no history of rheumatism at all. Much might be done with

mild cases of talipes by suitable light splints and massage and manipulations.—Mr. Clarke replied.—Dr. J. G. Pardoe then read a paper on the Use of the Retained Catheter in Some Lesions and Suppurations of the Male Urinary Passages. He said that in English literature relating to this subject there was a very inadequate account of a mode of treatment which was satisfactory, simple, and easy of application in certain diseases of the male urino-genital tract. He considered the application of the method first to the treatment and certain vesical conditions and, secondly, to morbid states of the urethra. It was most useful in all inflammatory conditions of the bladder in which pus was present in the urine. Constant drainage obviated the painful spasm present in these cases and allowed of frequent washing out of the bladder. Dr. Pardoe further advocated the use of the retained catheter in cases of complete prostate obstruction, congested prostates accompanied by hæmorrhage, and enlarged prostate complicated by stone in the bladder which necessitated the use of the lithotrite; in these cases one was able to more thoroughly evacuate the bladder of retained débris. He also urged its use in cases of suprapubic cystotomy, especially where primary suture of the bladder was performed. Cases of tuberculous and simple ulceration of the bladder were not favourable ones for this means of drainage and were often rendered worse by its use. He then described and advocated the more frequent use of the retained catheter in various urethral conditions, such as ruptured urethra, Syme's and Wheelhouse's operations, and more especially after the operation of internal urethrotomy. The majority of French surgeons, led by Guyon, insisted upon its use in this operation as a necessity. The points to be observed in carrying out this method were: (1) that the catheter should have a large lumen; (2) that it should have one or two large eyes; (3) that it be incompressible; and (4) that it should be capable of easy sterilisation. The best catheters to use were soft rubber ones, as Jacques' catheter or the best silk web catheters with two eyes. He insisted on the necessity of careful cleansing of the glans, prepuce, and meatus with some antiseptic previous to tying in the catheter which should not be passed too far. Four tapes should be tied on to the catheter and these fixed with a strip of strapping below the corona and the whole of the glans covered with antiseptic gauze. Pain resulting from a retained catheter was generally due to one of two causes: (1) intermittent or incomplete drainage, or (2) a badly fitting catheter.—The President thanked Dr. Pardoe for a very interesting and instructive paper. The practice suggested was in advance of ordinary teaching on the subject, and all present would be glad to feel that the use of the retained catheter was one which they could more freely fall back upon.—Dr. Alderson had found leeches to the anus very useful in cases of hæmorrhage from a congested prostate. He also advocated the use of boric acid internally when catheters were tied in as a means of keeping the urine sweet.—The President proposed a vote of thanks to Dr. Pardoe, which was carried.—Dr. Pardoe replied.

BRADFORD MEDICO-CHIRURGICAL SOCIETY.—A special meeting of this society was held on Nov. 27th, 1900, when an address was delivered by Professor Clifford Allbutt, F.R.S., on the Clinical Bearings of High Arterial Pressure.—The annual dinner was held after the meeting, at which Professor Allbutt and about 70 members and guests were present.—The ordinary monthly meeting was held on Dec. 18th, Mr. P. E. Miall being in the chair.—Dr. William Mitchell showed: (1) A Cast of the Genital Region from a case of Inguinal Hernia after the operation for "radical cure" had been performed; and (2) the Eyeball from a case of Perforating Ulcer of the Cornea.—Dr. C. F. M. Althorp showed the following:—1 A patient on whom he had operated for Irreducible Dislocation of the Proximal Phalanx of the Index Finger. The dislocation had been maintained by the glenoid ligament. The patient had almost perfect use of the finger and was able to use it for writing. 2. A child, aged seven years, with Secondary Deposit of Sarcoma in the Temporal Region. The forearm had been amputated for periosteal sarcoma of the radius six months previously.—Mr. W. H. Horrocks showed a specimen of Strangulation of a Loop of Intestine through an Aperture in the Mesentery The patient, a boy, aged 10 years, had a strangulated hernia which had been reduced under an anæsthetic. Pain and sudden collapse supervened a few hours after reduction of the hernia and the condition exhibited was found post mortem. The hernia had been successfully reduced.—Dr. A. Bronner showed: (1) Archer's Perimeter; and (2) a child whom he had operated on for Acute Empyema of the Frontal Sinus. The disease came on after scarlet fever and extensive caries of the bone was found at the operation.—Mr. Miall read notes on a case of Forced Delivery at the Seventh Month in Contracted Pelvis. The patient was 24 years of age and had been delivered two years previously by craniotomy. The pelvis was flattened and generally contracted, its measurements being: interior conjugate, three inches; distance between the spines of the ileum, eight and one-eighth inches; distance between the iliac crests, eight and a half inches; and external conjugate, nine and a quarter inches. An attempt to bring on labour was first made by introducing wood-wool and glycerine plugs into the cervix and also by injecting glycerine. No pains having occurred after four hours a screw dilator was introduced and the cervix dilated under chloroform until a medium sized Barnes's bag could be introduced. As soon as the hand could be introduced the membranes were ruptured and internal version performed. Delivery was soon effected and the child cried strongly. The uterus contracted well under pressure and the placenta was born 20 minutes after the child. The whole process, from the commencement of dilatation to the delivery of the placenta, only occupied one and a half hours. There were no spontaneous contractions of the uterus from first to last. The mother made a good recovery but the child died from debility at the end of 20 days. Mr. Miall considered that the procedure he adopted in this case was quite as safe and was more certain than the methods usually employed for inducing premature labour.—Dr. S. Johnston and Mr. R. Mercer discussed the case and Mr. Miall replied.—Dr. Bronner read notes on the Therapeutic Uses of Orthoform and Ferripyrin.—Dr. S. Lodge read notes on a case of Malignant Disease of the Œsophagus associated with Respiratory Obstruction in which both gastrostomy and tracheotomy had been performed. The patient was a woman, aged 60 years, with a stricture high up in the gullet. The stricture of the œsophagus was accompanied by abductor palsy of the vocal cords causing severe spasms of dyspnœa. The patient was alive and enjoying a fair measure of health six months after the gastrostomy.

NORTH OF ENGLAND GYNÆCOLOGICAL AND OBSTETRICAL SOCIETY.—A meeting of this society was held at Owens College, Manchester, on Dec. 21st, 1900, Dr. J. B. Hellier, the President, being in the chair.—Dr. D. Lloyd Roberts (Manchester) showed a Three Months' Fœtus and Placenta from a case of Ruptured Ectopic Gestation. Abdominal section was performed on account of profuse intra-peritoneal hæmorrhage. This bleeding was found to arise from the partially detached placenta and not from the ruptured Fallopian tube.—Dr. J. E. Gemmell (Liverpool) showed the Appendages removed by Abdominal Section from a case of Inflammatory Disease of the Tubes and Ovaries. The case was of interest inasmuch as the inflammatory masses occupied the pouch of Douglas and protruded through the vulval orifice, resembling at first sight a prolapsed retroverted uterus.—Dr. J. W. Martin (Sheffield) showed a Solid Ovarian Tumour removed from a girl, aged 17 years. The tumour weighed three and a half pounds and was non-adherent. Microscopically it was found to be a round-celled sarcoma.—The President gave an address entitled: "On Infection of the Genital Canal." He said that the study of the pathogenic organisms of the genital tract had brought their knowledge of puerperal diseases into a line with general surgical pathology, and the so-called "puerperal fever" was no longer the mystery which it was formerly held to be. They now knew that with aseptic precautions even the pregnant uterus and its appendages could be safely subjected to surgical operations. In a recently delivered woman they had a long sinus leading to a large wound surface. The walls of this tract were often bruised and had their vitality diminished, and in the fundus uteri was a collection of fluid and blood-clot, with portions of necrosing tissue—a choice breeding-ground for any micro-organisms which might effect an entrance. Further, the large plexuses of lymphatic vessels and the patent Fallopian tubes favoured an extensive invasion of the micro-organisms. The germs of puerperal fever were precisely those of ordinary surgical wound infection, and the conditions of success in modern midwifery were the same as those which

had revolutionised surgery—viz., personal asepsis of the surgeon and nurses, the sterilisation of instruments, and the minimum of interference and manipulation. The systematic cleansing of the genital canal before delivery had not given such good results as leaving well alone. The most important factor in the conveyance of puerperal infection was the hand of the attendant. The President drew attention to the great difficulty of obtaining sterility of the hands, as shown by recent observations, nor was it yet decided how soon they might safely attend a puerperal case after exposure of the hand to a septic infection. The frequency of puerperal infection was largely attributable to the unsanitary conditions of the patients, their clothing, beds, and surroundings. Recent researches had demonstrated the great resisting power of the tissues of the genital canal to infection, and there was no doubt that the large majority of cases of infection recovered spontaneously or with suitable local treatment. The importance of gonorrhœa as a factor in causing infection of the genital canal had been clearly shown in recent years and in former days there was little doubt that infection had frequently been conveyed directly from patient to patient by specula, instruments, &c. It was most probable that in health the genital canal was aseptic or at least contained no pathogenic organisms. The President also drew attention to the harmful effects of foreign bodies in the vagina, such as pessaries, and especially uterine stems, inasmuch as they seriously interfered with the bactericidal effect of the healthy vaginal secretion and so lead to infection.

BRITISH ORTHOPÆDIC SOCIETY.—The twenty-fourth ordinary general meeting of this society was held at the National Orthopædic Hospital, Great Portland-street, W., on Dec. 15th, 1900, Mr. D'Arcy Power being in the chair.—Mr. E. Muirhead Little showed a patient suffering from Infantile Paralysis of the Left Upper Extremity wearing an ingenious instrument which considerably aided the use of the limb.—Mr. H. A. Reeves opened a discussion on Congenital Defects of the Skeleton. Commencing at the skull and face, he passed rapidly over all important skeletal defects, laying stress on those which were amenable to surgical treatment. His remarks were illustrated by much material and a copious supply of photographs and radiographs. Dealing with the spine Mr. Reeves stated that cases of wryneck and lateral and anterior or posterior curvature were due to deficiency of parts of the vertebral bodies as shown by existing specimens, that the direction of the deviation was determined by whether the defect was lateral or in front, and that usually a wedge-shaped piece of bone was found detached just as occurred in latent deviation of the fingers and toes. The treatment consisted in keeping the neck and spine in a correct position so as to prevent further contraction of muscles and ligaments on the curved side. Hour-glass contraction in the thorax and congenital epigastric depression were to be treated by respiratory exercises and spinal manipulations acting through the ribs if the child were old enough to be taught. He pointed out that in the upper limb the high position of the scapula, whether single or double, was to be treated by manually depressing the bones so as to stretch the muscles, and said that though the malposition was called in Germany "Sprengel's malady" his paper on it had appeared in 1891 while Mr. Reeves had described it in 1885. He mentioned that exostosis of the vertebræ was often present. Intra-uterine fractures, rickets, congenital dislocations of the shoulder, and absence of the clavicles and bones of the upper limb were then dealt with, and also the treatment of club-hand. Finger deviations, syndactyly, polydactyly, brachydactyly, and megalodactyly and their treatment were gone into, and the statement was made that, as a rule, the flap operation for united fingers was not very satisfactory because of the inequality of the adjacent digits. Defects of the pelvis were usually secondary and had more gynæcological than orthopædic interest. In the lower limb absence or deficiency of the femur, congenital misplacement of the hip, coxa vara and coxa valga, absence or misplacement of the patella, genu recurvatum, and other knee displacements and their treatment were entered into. Absence, partial or complete, of the fibula or the tibia, fusion of the bones, and platycnemic tibia and their treatment were discussed, also the rare condition of congenital displacement of the ankle. Congenital amputations and the grooves formed by strangulation by the umbilical cord were alluded to, and the various deformities of the feet were described and their treatment discussed. Mr. Reeves also explained three new operations for paralytic calcaneus and calcaneo-cavus.—Mr. D'Arcy Power, Mr. Muirhead Little, Mr. C. R. B. Keetley, and Dr. A. F. Blagg joined in the discussion on the paper.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.—A meeting of this society was held on Dec. 20th, 1900, Dr. Wearne Clarke, the President, being in the chair.—The following specimens were shown. Dr. Sinclair White: (1) Sarcoma of the Scapula; (2) Sarcoma of the Fibula; (3) Carcinoma of the Intestine; (4) Deciduoma Malignum; and (5) Femur showing Central Necrotic Caries.—Dr. Wilkinson: (1) Stone in the Kidney; (2) Cystic Thyroid; (3) Rodent Ulcer; and (4) Carcinoma of the Mammæ.—Mr. Connell (specimens from the Museum of the Pathology Department): (1) Secondary Sarcoma (Melanotic) of the Vertebræ; (2) Secondary Carcinoma of the Vertebræ; (3) Chest Wall and Right Radius from a case of Rickets; (4) Varieties of Inflammation of the Vermiform Appendix; (5) Sarcoma of the Lower Jaw; and (6) Sarcoma of the Metacarpus.—Dr. T. H. Morton: Drawings and Photographs.—Mr. Simeon Snell: (1) Carcinoma of the Eyeball; (2) Pedunculated Dermoid of the Conjunctiva; and (3) Epithelioma.—Dr. W. M. Robertshaw: Portion of the Lung of a Ganister Worker.—Dr. Godfrey Carter: (1) Spinal Cord (degeneration); (2) Fatty Heart (fatal chloroform anæsthesia); (3) Lardaceous Kidney; and (4) Atrophied Gastric Glands (pernicious anæmia).—Mr. Alfred Reckless: Micrococci in Pneumonic Sputum.—Dr. Gilmour: (1) Heart, Lung, and Liver from a case of Mitral Stenosis; (2) Tumour of the Thyroid; and (3) Porenchephaly.—Dr. J. Robertson: Highly Charged Tuberculous Sputa.—Dr. A. Hall showed the following specimens from the collection of the Pathological Museum, University College: (1) Fibrosis of the Heart (syphilitic); (2) Heart (congenital syphilis); (3) Heart with large Thrombus on the Mitral Valve; (4) Heart with Ball-thrombus in the Left Auricle; (5) Heart with Calcareous Coronaries; (6) Bovine Heart; (7) Spleens, with infarcts, simple and malignant; and (8) Salivary Calculus.—Dr. Hall also showed various microscopical sections, including: (1) Rodent Ulcer; (2) Lupus; (3) Miliaria of the Skin; (4) Blood Films; and (5) Various Tumours, &c.—Dr. Hall also gave a short account of the material sent in for examination to the Pathological Department of University College, Sheffield, during the year.—Dr. J. Robertson read a note on the Work done at the Bacteriological Laboratory in connexion with University College, Sheffield, since its commencement. Courses of instruction for medical students, post-graduate courses, and diplomate of public health courses had been held. During the past 18 months 1605 swabs had been examined for various sanitary authorities from patients suspected to be suffering from diphtheria, nearly 500 specimens of blood had been examined for serum reaction, and 663 specimens of sputum had been examined for tubercle. In addition to this numerous articles had been received for bacteriological examination and certain research work was undertaken.

ROCHDALE AND DISTRICT MEDICAL SOCIETY.—A meeting of this society was held on Jan. 3rd, when Dr. W. E. Jameson read a paper on Anthrax, with special reference to a case of malignant pustule which had recently occurred in his own practice. The source of infection was China skins and the diagnosis was confirmed bacteriologically. The only unusual symptom was suppression of urine lasting for 36 hours. The treatment consisted in excision of the pustule and the application of pure carbolic acid to the wound, with general stimulants internally. The patient died from exhaustion.—Mr. Wilton Mills mentioned a case in which the poison entered by a small burn on the cheek.—Dr. A. Wallace, Mr. G. W. Malim, and Mr. W. Stanwell also joined in the discussion.—Dr. Jameson also read notes on a case of Ovarian Cyst occurring in a phthisical patient. The cyst grew for over two years. The patient was then seized with abdominal pains, and profuse watery diarrhœa began and lasted for 11 days, during which the tumour gradually disappeared. Dr. Jameson believed that the cyst, the existence of which had been confirmed by Dr. A. Donald, had ruptured into the bowel, but although the patient died from phthisis 15 days later a post-mortem examination was not obtained and the theory remained unconfirmed.—Mr. S. T. Lord and Dr. Wallace discussed the case.

Reviews and Notices of Books.

Text-book of Physiology. By British Physiologists. Edited by E. A. SCHÄFER, LL.D. Aberd., F.R.S., Professor of Physiology, University of Edinburgh. Volume II. With 449 Illustrations. Edinburgh and London: Young J. Pentland. 1900. Pp. 1365. Price 42*s*.

THIS work is rather to be regarded as an encyclopædia than a text-book, for it contains an account of physiology which embraces every department of that science, whilst the several sections having been placed by the editor in the hands of writers whose attention has been specially occupied in developing the subject with which they have been intrusted secures a fulness and accuracy that would have been otherwise unattainable. Thus the Mechanism of the Circulation of the Blood has been written by Dr. Leonard Hill; the Contraction of Cardiac Muscle by Dr. W. H. Gaskell; Animal Mechanics and the Sense of Taste and Smell by Professor J. B. Haycraft; the Muscular and Nervous Mechanism of the Respiratory Movements and that of the Digestive, Urinary, and Generative Tracts by Dr. E. H. Starling; the Mechanical, Thermal, and Electrical Properties of Striped Muscle by Sir J. Burdon Sanderson; Nerve and the Physiology of Electrical Organs by Professor Francis Gotch; the Nerve Cell and the Cerebral Cortex by the editor, Professor E. A. Schäfer; the Sympathetic and other related Systems of Nerves by Professor J. N. Langley; the Spinal Cord and the Parts of the Brain below the Cerebral Cortex, Cutaneous Sense and the Muscular Sense, by Professor C. S. Sherrington; Vision by Dr. W. H. R. Rivers; and the Ears and Vocal Sounds by Professor John Gray M'Kendrick and Dr. Albert A. Gray.

It must strike all who read this volume that as physiology is becoming more and more a specialised branch of knowledge many lines of research which have been pursued with great zeal have apparently but a remote bearing on medical practice and are in themselves too abstruse for the ordinary practitioner to master, unless he have special proclivities for scientific research. Still, in the history of science many instances might be quoted where the cultivation of dry and arid fields of research has been rewarded by a harvest of interesting and useful results. It is well, therefore, that from time to time a general review of the state of physiological science, as taught and understood by its chief exponents, should be written. The present volume is to a very large extent occupied with the consideration of the nervous system, long articles being devoted to the nerve-cell, to the nerve-centres, and to the senses. There is, of course, a considerable quantity of original investigation by the several authors, but the bulk of the book is taken up with recent investigations in France, and especially in Germany.

One of the most interesting chapters is by the editor, Professor Schäfer, and is devoted to the cerebral cortex. In it is given, succinctly and yet clearly, the very considerable increase in our knowledge of the functions of the cortex that has accumulated in the course of the last 30 years. Some of the results of the application of modern methods of investigation are more than surprising. At first sight, for instance, it would not be thought possible that any rational idea could be obtained of the duration of action of a nerve cell of the cerebral cortex, yet there is reason to believe that it can be estimated with some approach to accuracy from the consideration of the waves that are seen in a graphic tracing of a voluntary muscle when made to contract by the influence of the will. The successive contractions are found to vary from 8 to 13 or even 20 in a second, 10 being the average. This number is also supported by the rate of contraction in shivering and that it is impossible to articulate at a greater rate than 11 syllables per second, hence it may be concluded that the average interval between the consecutive nervous discharges from the cortical cells is 0·1 second and the minimal interval 0·05 second, and that this rapidity corresponds with the impulses originating in the cells of the brain appears probable from the circumstance pointed out by Richet that it is impossible to *think* the act of articulation at a greater rate than this, and the same statement applies to the thinking the act of singing or of playing a series of musical notes. Professor Schäfer gives a comprehensive view of other phenomena that have been observed on stimulation of the cerebral cortex, including the experiments of I. Munk and W. G. Spencer showing the effects on respiration, and Professor Schäfer's own observations in conjunction with Dr. J. R. Bradford showing the effects on the circulation, on the pupil, on secretion, and on heat. The whole subject of localisation in the cortex cerebri is, as might be expected, very fully given, and shows how much has been done in this direction by the well-directed experiments of recent observers.

The volume opens with a long and carefully written article by Dr. Leonard Hill on the Mechanism of the Circulation of the Blood. The problem of the cause of the first sound of the heart seems to be no nearer solution than it was half a century ago. All seem to be agreed that the second sound is purely valvular, but Dr. Hill enumerates no less than nine events, each of which has been regarded as the efficient cause of the first sound, the sudden tension of the auriculo-ventricular valves being placed, perhaps without any significance being attached to its position, eighth on the list, though it is certainly the most important. The experiments of Wintrich with resonators long ago established the fact that the first sound is complex and really consists of two sounds, of which one is of higher pitch than the other, and hence it seems reasonable to maintain that it is due not only to the sudden tension of the auriculo-ventricular valves but to the friction of the vast mass of muscular fibres running in different directions over each other. Such events as the tension of the blood caused by a collision of the blood particles in the ventricles, the sudden collision of the ventricular contents with the column of blood in the aorta and pulmonary artery, and the rest may surely be disregarded, their contribution to swell the volume of the second sound being doubtful or altogether trifling. Dr. Hill, however, whilst admitting the two causes above-named as the efficient ones, seems inclined to think that the impulse of the heart against the walls of the chest may be an occasional and auxiliary cause. The article contains many interesting facts that have been established in late years partly by Dr. Hill's own labours and partly by those of others. For example, he points out that the phenomena observed in sphygmographic and manometric tracings present certain difficulties in their explanation. These discrepancies may be reconciled if it be clearly understood that the veins which surround the radial artery bear an important share in the production of the pulse; and, he continues, the condition of the veins must exert an important influence in all pathological states of obstruction of the circulation from pulmonary or cardiac disease.

In the succeeding article by Dr. Gaskell on the Contraction of the Cardiac Muscle the reader will find all that is at present known in regard to the augmentor and inhibitory nerves of the heart.

An interesting and valuable chapter, containing as it does the results of much original investigation, is contributed by Sir J. Burdon Sanderson on the Mechanical, Thermal, and Electrical Properties of Striped Muscle. The phenomena of the contraction of muscle under the influence of a continuous impulse or in a state of tetanus are considered; then the more complex conditions resulting from a single instantaneous stimulus, the graphic tracings being obtained both

by Fick's cosine lever and Blix's apparatus for recording the movements of the style attached to the muscle. Sir J. Burdon Sanderson believes that the wave of contraction travels in the muscles of the frog at about three metres per second and that in the rabbit the rate of propagation is 3·4 metres for the red muscle and 11 metres for the white. The different forms of isometric and isotonic curves of muscles—that is to say, of muscles attached at both extremities or free at one extremity and either unweighted or weighted—are given. Sir J. Burdon Sanderson's own experiments on the duration of the latent period of contraction in muscle are detailed in which he showed that instead of that duration being two- or three-hundredths of a second, as Helmholtz thought, it is not really more than three- or four-thousandths of a second. The characters of fatigue in muscle and its response to various forms of electrical stimulation are described in full.

We learn from Professor Starling's Muscular and Nervous Mechanism of the Respiratory Movements that from the results of researches and experiments made by several observers Flourens' *nœud vital* is very much more extensive than the small region in which that savant located the respiratory centre. It probably occupies a very considerable area of the *formatio reticularis* at the level of the lower part of the fourth ventricle. Speaking of the vexed question of the cause of the continuance of the respiratory acts after section of the vagi and the cord in the lower part of the cervical region and of the medulla oblongata just below the pons, that is, of nearly all sensory paths of excitation, the complex nature of the problem is rendered evident by the want of concordance in the results obtained by different experimenters. It is not as yet quite satisfactorily determined whether the pulmonary branches of the vagus transmit normally impressions which lead to inhibition of the respiratory movements, that is, to expiratory efforts or to inspiratory efforts.

Few chapters on physiology have undergone more extension than that dealing with the sympathetic system, and this subject has now been very completely considered by Professor J. N. Langley. The structure of the cells is given by Professor Schäfer in another article, but the details of the origin of this system from the spinal cord, the distribution and function of it, are all fully described by Professor Langley.

The chapter on the Muscular Sense by Professor Sherrington gives the various opinions that have been held on the nature of this sense—that, for example, of Bain and Helmholtz, which dispenses with peripheral organs and afferent nerves; that held by Schiff, that this sense has no apparatus of its own, but that it results from sensations derived from the sense organs of the other five senses; and thirdly, that held by Professor Sherrington himself, that the "sense" is based on a specific set of sensations obtained by specific sense organs in muscles, tendons, joints, and all the accessory organs of movement. From the results of sections causing degeneration of nerve fibres Professor Sherrington found that from one-quarter to one-half of all the nerve-fibres in nerves supplying muscle to be sensory. The peripheral sense organs are the Pacinian bodies, Golgi organs, and muscle spindles. Professor Sherrington makes some observations on the "knee-jerk" and holds that it is not a reflex act, but is, nevertheless, dependent on a reflex spinal arc, the afferent part of which is based on sense organs in the muscle itself and its appurtenances. It has been the subject of many investigations and Professor Sherrington has accumulated many facts concerning it. Its absence is often an indication of disease, yet in some persons who are apparently healthy the movement cannot be elicited. The special senses are very fully and admirably treated. Dr. Rivers gives at considerable length the views of Helmholtz and Tscherning on the nature of the accommodation of the eye but does not pronounce definitely in favour of either. In fact, the arguments seem nearly of equal weight for either theory. The volume concludes with remarkably complete and useful indices which must have taken much time and required the expenditure of much thought to make. Professor Schäfer may congratulate himself on having made a valuable contribution to English physiological literature.

A Text-book of Embryology for Students of Medicine. By JOHN CLEMENT HEISLER, M.D., Professor of Anatomy in the Medico-Chirurgical College, Philadelphia. With 190 Illustrations, 26 of them in colours. London and Philadelphia: W. B. Saunders. 1899. Pp. 405. Price 10*s.* 6*d.* net.

THIS work contains a plain, straightforward, and very intelligible account of the process of development in man. The early stages are, of course, chiefly drawn from the appearances presented by the egg of the fowl and lower animals and the description is generalised, but from the formation of the amnion and allantois the conditions of the human subject are kept steadily in view, and it is essentially the development of the human embryo that is followed. The drawings illustrating the text—so important in an embryological treatise—are numerous and have been well selected from His, Tourneux, Waldeyer, and others, but there are some original sketches and many diagrams which will prove of service to the student. The early stages are given in moderate detail and the mode in which the author introduces observations that have a direct relation to practice is to be specially noted.

The menstrual cycle of 28 days, for example, Dr. Heisler considers may be divided into four periods: the constructive stage, comprising from five to seven days, during which the mucous membrane of the uterus becomes to a marked extent swollen, the tissue more vascular, and the glands wider and longer; the destructive stage, which lasts about five days and commences with infiltration of blood into the subepithelial tissue, probably by diapedesis, which is followed by partial disintegration of the mucous membrane, exposure and rupture of the blood-vessels, causing the hæmorrhage; the stage of repair, occupying the three or four days following the discharge and characterised by the growth of new tissue; and lastly, the stage of quiescence, which extends from the close of the preceding stage to the end of the cycle. The relation of menstruation to ovulation and conception is briefly but very clearly given. The duration of pregnancy is given, of course, at ten lunar months, and it dates from the moment of conception; but since the ovum retains its vitality for about a week after its extrusion from the Graafian follicle, and since the spermatozoa may remain active for several weeks after their entry into the female genital tract, it is impossible to fix within a week or two weeks the date of conception even where there has been only one coitus. A similar relation of the history of the process of development to practice is shown in the account of the process of cleavage. Partial longitudinal division of the embryonic area, from which alone, the author has just explained, the body of the embryo is developed, results in the production of some form of double monster; its complete cleavage gives rise to homologous or homogeneous twins, which are twins of the same sex and of almost absolutely identical structure. Ordinary twins are developed from separate ova which may or may not have come from the same ovary. In regard to the formation of the mesoderm Dr. Heisler agrees with Bonnet and Duval, holding that the mesoderm originates from a double source, chiefly from the entoderm, but also from the ectoderm, since the cells giving rise to the part that grows from the region of Hensen's node are ectodermic. After its formation the mesoderm grows by the proliferation of its own cells independently of the ectoderm and the entoderm and the structures derived from it are connective tissue in

all its forms, including cartilage, fibrous and elastic tissue, bone, dentine, lymph, blood, muscle, all endothelial cells, the spleen, kidney, and ureter, the testis and its excretory ducts, the ovary, Fallopian tube, uterus, and vagina. Speaking of the allantois, after describing its mode of origin, he shows how it becomes a pedunculated sac lying in the extra-embryonic part of the cœlom, the peduncle leaving the body cavity proper through the umbilical opening; how its walls are composed of entoderm and visceral mesoderm; how its blood-vessels develop in the mesodermic stratum; and how its union with the false amnion produces the true chorion. Dr. Heisler then continues: "The human allantois presents a striking peculiarity as compared with that of birds and reptiles; in man the allantois develops not as a free sac projecting into the extra-embryonic body cavity but as a mass of splanchno-pleuric tissue, which contains only a rudimentary cavity and which grows into the abdominal stalk, being guided by that structure to the false amnion." Illustrations of this are given. The function of the allantois is stated to be that it serves as a nutritive and respiratory organ until the formation of the placenta, its period of activity extending from about the fifth or sixth week to the third month; it also constitutes a receptacle for the fœtal urine, and it produces three structures of the adult organism, the urachus, the urinary bladder, and the first part of the urethra of the male and the entire female urethra. The chapter on the development of the heart and vascular system is very complete, as is also that of the alimentary canal and its appendages. The remaining systems are considered in the following order: the respiratory, genito-urinary, cutaneous, nervous, including the special senses, the muscular and osseous. In a tabulated chronology at the close of the book each of these systems is described as it appears every week up to the ninth week, and subsequently at the end of every month up to maturity. Throughout the work the author is careful to give explanations of the mode of origin of such deformities as cleft sternum, cleft palate, hare-lip, and ectopia of the intestines and bladder, and the reader will find definitions of many terms that have recently been introduced, such as prochorion, ameloblasts, dermal navel, paraxial mesoderm, and the like. There is an excellent index, yet "blastodermic vesicle" is omitted. It would be a convenience, as there are many references to figures, to give the page on which each is to be found, as much time is lost in looking for one perhaps 10 pages in advance. The work as a whole may be regarded as giving an excellent presentment of the present state of embryological knowledge.

Materia Medica for India. By C. F. PONDER, M.B., C.M. Edin., and D. HOOPER, F.C.S., F.L.S. Calcutta: Thacker, Spink, and Co. 1900. Pp. 356. Price 6*s*.

THIS volume has been issued as an Indian companion to the British Pharmacopœia of 1898, and contains, in addition to the officinal preparations, 350 of the better known Indian drugs, many of which the authors consider to be capable of employment as substitutes. The medicinal properties of the various substances are given in brief, and the authors acknowledge having used Sir T. Lauder Brunton's "Manual of Pharmacology, Therapeutics, and Materia Medica" as an authority here in many cases. We presume that the medicinal properties of the indigenous drugs, the use of which has not reached the west, are stated upon similarly good grounds. In some cases these properties are not familiar to us, and we should have liked to see some authority for the statements. The arrangement of the book is neat and practical. All preparations in the vegetable materia medica are placed in one article under the heading of the botanical parent, and in the same manner the active principles are discussed under the heads of their respective raw products. All the salts of a metallic substance are dealt with under their bases. The addition of tables of weights and measures and a few simple notes on pharmacy will make the book valuable to medical men not anxious to burden themselves with a multiplicity of text-books.

Studies in the Psychology of Sex. By HAVELOCK ELLIS. Philadelphia: F. A. Davis Company. Pp. 275. Price $2.00 net. (Sold only to Physicians and Lawyers.)

THIS volume contains three studies entitled the Evolution of Modesty, the Phenomena of Sexual Periodicity, and Auto-Erotism respectively. The first study is a really close inquiry into an important phase of modern manners. Many authors before Mr. Havelock Ellis have suggested that what we nowadays call modesty is exactly the most important factor in woman's sexual attractiveness to man, but no one has ever given such a multitude of examples in proof of the proposition that the woman of to-day's civilisation is not ashamed to be seen naked because she is naked, but only because she is without her weapons of seduction. The next section of the book—the study of the evidence that the sexual functions of man are periodic—is also interesting and displays its author as deeply read in many by-ways of physiology and psychology. We agree with him that it is not yet demonstrable that a sexual rhythm similar to that which occurs in woman occurs in man, but we do not think it nearly as probable as he does that the existence of such a cycle will be proved. The testimony of those willing to give it would be very untrustworthy, and the personal equation enters so largely, as we have recently had to point out, into the matter of sexual appetite that we cannot conceive any natural law regulating the human race. The last part of the book is devoted to an elaborate investigation into the causes of masturbation. This delicate subject is treated by Mr. Havelock Ellis with thoroughness and decency. Most of what he has written will be familiar to medical men because of the confidences that have been reposed in them, but the essay is very suggestive in its indications of advice and general treatment. Strictly medical advice, we are glad to see, it is not attempted to give.

This contribution to our comprehension of sexual psychology is to be sold only to physicians and lawyers. We trust that the publishers will take every pains to observe the restrictions of sale that they have laid down for themselves. Mr. Havelock Ellis has written a book that has its distinct uses, and he has done his work in a proper manner, saying clearly what must be said, and neither making mock-modest moans over the depravity of the human race nor relating "good" stories under the guise of scientific evidence. But his book must not be sold to the public, for the reading and discussion of such topics are dangerous. The young and the weak would not be fortified in their purity by the knowledge that they would gain from these studies, while they certainly might be more open to temptation after the perusal of more than one of the chapters.

Ulceration of the Bladder, Simple, Tuberculous, and Malignant. By E. HURRY FENWICK, F.R.C.S. Eng., Surgeon to the London Hospital, Surgeon and Pathologist to St. Peter's Hospital for Urinary Diseases, &c. London: J. & A. Churchill. 1900. 8vo. Pp. 85. Price 5*s*.

IT was not until the invention of the cystoscope that we had anything other than a post-mortem knowledge of ulceration of the bladder; and though the diagnosis of tuberculous or simple ulceration was occasionally made, yet the diagnosis was nearly always rather uncertain. Even with the aid of the cystoscope the difficulty of diagnosis is not at an end, for it is very difficult when ulceration is present to obtain the contents of the bladder in a perfectly clear condition, so that the state of the vesical wall may be

distinctly examined. The introduction of the cystoscope is liable to be especially painful when there is a tuberculous ulcer in the bladder and this does not appear to be generally due to any extension of the disease into the urethra.

Mr. Fenwick lays stress on the possible dangers of instrumentation in non-malignant ulceration of the bladder, and he shows that the viscus is extremely liable to tear, and he suggests that before the anæsthetic is administered the surgeon should ascertain how much urine the patient can pass at one time; then if an ounce be added to represent the residual urine the total should be about the quantity injected and withdrawn in washing. This is certainly a safe method, but equal safety is obtainable by limiting the pressure of the contents on the bladder wall to a safe amount. The pressure can always be exactly known by the use of a funnel and tube for filling the bladder. If the height of the funnel above the bladder does not exceed two feet the internal vesical pressure cannot exceed one pound on the square inch. If, however, a syringe be employed to fill the bladder it is quite impossible to gauge the pressure with any accuracy.

The author divides the non-malignant ulcers into "simple" and "tuberculous." The simple ulcers he again divide into "spontaneous," as in the solitary simple ulcer, and the "consecutive," as in those following on cystitis or prostatitis. Mr. Fenwick compares the solitary simple ulceration of the bladder to the simple ulcer of the stomach. He has met with it chiefly in young men about 20 years old. It gives rise to marked hæmaturia and frequent micturition and causes much puckering when healed. The prognosis of this ulcer is very good, and the author advises curetting in all except the most advanced stages.

The tuberculous ulcers are divisible into those which are primary and those which are consecutive to tuberculosis elsewhere. For the primary form Mr. Fenwick advises that sandal oil should be administered for about a fortnight to reduce inflammatory swelling, then five grains of hexamethylene tetramine in half a pint of hot water are to be given three times a day to render the urine acid and if possible aseptic. For the localised form then Koch's "new tuberculin" is to be used, and if after six injections the ulcer shows signs of healing then it may be left, but if not it is to be scraped, through a suprapubic incision in the male and through the dilated urethra in the female. If the tuberculous ulceration is diffuse, the author considers that no cutting operation should be carried out, but Koch's tubers culin should be injected.

For malignant ulceration of the bladder in advanced cases Mr. Fenwick considers that "detrusotomy"—that is, removal of two-thirds of the detrusor muscle of the bladder by a transverse suprapubic incision—offers the greatest chance of relief.

The book deals with a difficult subject and contains many original observations and suggestions which deserve careful consideration from surgeons. A full discussion of the work would extend far beyond the limits of a review, but we have endeavoured to present the author's opinions on a few of the more important matters with which he deals.

LIBRARY TABLE.

Appendicitis and its Surgical Treatment, with a Report of 185 Operated Cases. By HERMAN MYNTER, M.D. Copenhagen, Professor of Clinical Surgery in the University of Buffalo, New York. Third Edition. Philadelphia and London: J. B. Lippincott Company. 1900. Pp. 226 and Index. Price 10*s.* 6*d.*—This book formed the author's graduation thesis at the University of Copenhagen. It is, in fact, a careful study and estimation of the evidence for and against the operative treatment of appendicitis. The anatomy, histology, etiology, pathology, classification, symptomatology, complications and sequelæ, diagnosis, prognosis, and treatment are all considered, and the author's conclusions are as follows:—"There is a point of time in every case of appendicitis at which recovery is possible by operation. The prognosis depends solely upon this point of time. ..... We cannot operate too early, we are often too late ..... the only reliable help is to be found in surgical treatment. The earlier the operation is performed the better is the prognosis and the surer the recovery—a recovery, too, which is radical." The book is a valuable and summarised compendium of the views of medical men up to the present time upon the important question with which it deals.

Rheumatism, Rheumatoid Arthritis, and Subcutaneous Nodules. By C. O. HAWTHORNE, M.D. Glasg., M.R.C.P. Lond. London: J. & A. Churchill. 1900. Illustrated. Pp. 53. Price 2*s.* 6*d.*—The greater part of this essay appeared in the columns of the *Physician and Surgeon*, and, as the author admits, the matter dealt with is doctrinal rather than practical The subject discussed is the relationship of rheumatoid arthritis to other recognised rheumatic conditions, and inasmuch as no rigid line of distinction can be drawn between the so-called rheumatic nodules and the subcutaneous tumours which are found in cases of rheumatoid arthritis we are forced to the conclusion that either these nodules are not pathognomonic of rheumatism or that rheumatoid arthritis is only a modified manifestation of the rheumatic state.

Whitaker's Almanack. 1901. 12, Warwick-lane, Paternoster-row.—Like all the truly great "Whitaker" is at the same time modest. The title-page of his almanack merely states the following: "An almanack for the year of Our Lord 1901, by Joseph Whitaker, F.S.A., containing an account of the astronomical and other phenomena, a large amount of information respecting the Government, finances, population, commerce, and general statistics of the British Empire throughout the world, with some notice of other countries, &c., &c." As this incomparable work contains information upon every possible subject from celestial phenomena down to statistics of the Mormons, it will be seen that the "&c." comprises a great deal. We need say no more except that the present issue of the almanack is, if possible, better than any of its predecessors. It is really indispensable to all business men, and to our mind no one need be dull who has a copy by him to read.

Estudios Médico-Legales sobre el Código Civil Argentino. Por FRANCISCO DE VEYGA, Profesor de Medicina Legal de la Facultad de Ciencias Médicas de Buenos Aires, Cirujano de Ejército. (*Studies in Forensic Medicine according to the Civil Code of Argentina.* By FRANCISCO DE VEYGA, Professor of Forensic Medicine at the Faculty of the Medical Sciences of Buenos Aires, Surgeon to the Army). Buenos Aires: Libreria Cientifica de Augustin Etchepareborda. 1900. Pp. 557.—This book is a sort of commentary upon the civil code of the Argentine Republic in so far, that is, as it deals with medical or allied subjects. Professor de Veyga commences by giving a short history of the code, the study of which is, he says, imperative as a preliminary to the study of legal medicine and, moreover, for every medical man, whether especially concerned with forensic medicine or not. The remaining chapters of the book are taken up by the consideration of the usual subjects treated in books of forensic medicine, such as pregnancy, viability, minors, marriage, and the like. There is a chapter upon deaf-mutes who are not considered by the Argentine code as capable for "acts of civil life unless they can be communicated with and make themselves understood by writing." Another chapter of interest is one dealing with such questions as the recovery of fees and the right of medical men to receive legacies from their clients. From this we learn that medical men stand upon the same footing as any other class

of society in being able to inherit or to receive gifts from their clients. The book is very clearly and simply written and should be of value to those who live under the laws with which it deals.

Herbert Fry's Royal Guide to the London Charities. Edited by JOHN LANE. London: Chatto and Windus. 1901. Pp. 389. Price 1*s.* 6*d.*—This, the thirty-seventh, edition of an admirable little book differs but slightly from its predecessors. Its aim, as the editor states in his preface, is to point out to the suffering poor, in a book so cheap that they can either purchase it or get access to it, the place where they may obtain relief; and, secondly, to help benevolent people who have money to give but are doubtful where to bestow it. It will certainly serve these purposes, as it contains details of charitable institutions of all kinds and in addition information about societies which can in no way lay claim to that name. But this last foible it shares with other guides to charities and the inclusion does not impair the usefulness of the book.

Illustrated Lectures on Nursing and Hygiene. By R. L. ROBERTS, M.D. Lond. Third Edition. London: H. K. Lewis. Crown 8vo. Illustrated. 1900. Pp. 213. Price 2*s.* 6*d.*—This book is published as a companion volume to "Ambulance Work," and its contents are arranged in conformity with the syllabus of the advanced nursing course of the St. John Ambulance Association. The two first editions of this work have been largely instrumental in teaching the qualified members of the brigade their duties in general nursing and the care of the sick and wounded. The solid fact that over 1000 men of the St. John Ambulance Brigade have left this country for South Africa as hospital orderlies, nurses, and the like, and have shown considerable efficiency in their work, bears witness to the excellence of the institution and the books of instruction whereby the members are taught, and of these books few fulfil their object better than Dr. Roberts's "Illustrated Lectures on Nursing and Hygiene."

A National Question: Army Reorganisation (reprinted from *Blackwood's Magazine*). Edinburgh and London: William Blackwood and Sons. 1890. Pp. 32. Price 4*d.*—Amid the shoal of books and papers called forth by the present war, this little pamphlet, reprinted from *Blackwood's Magazine*, strikes us as unusually worth reading. The author advocates a change in our military system by which the home army shall be maintained on such a footing that it shall be always ready to take the field on short notice. The present system is based on a policy technically known as "defensive," as briefly outlined in "The Army Book for the British Empire," issued officially in 1893; whereas the author contends that it should in principle be "offensive" in the sense that any defensive policy should include a provision for the home army taking the field immediately on the outbreak of war; and he points out the changes believed to be necessary in order to secure this. His arguments have no direct or special bearing upon the medical services. The author is evidently keenly in earnest about the views he advocates.

"*Who's Who*" *for 1901.* London: A. and C. Black. Price 5*s.*—The 1901 volume of this useful book is larger than that of last year, chiefly on account of the incorporation with it of "Men and Women of the Time," and biographies of all Companions of Orders not previously inserted. We notice that the list of names headed, "The Victoria Cross" is incomplete. No names are given of either privates or of non-commissioned officers, an omission which seems to us unfair. The book, however, will be found to be specially useful to journalists, for it contains all sorts of information upon the press, both daily and periodical. There are also details of matters which are constantly being referred to, such as the Church, Government officials, metropolitan and provincial magistrates, a complete list of public schools and the various societies and their secretaries. The biographies, which are mostly autobiographic, also tell the seeker after knowledge everything about everybody who has ever done anything important, and about some others as well. It would be easy to point to biographies that are too short and biographies that are too long, supposing that the relative importance of the subject was intended to be gauged by the length of his or her memoir, but as this is nowhere stated the only comment that is necessary is that the great people are the most reserved. "Who's Who" is a valuable compilation, as all journalists have found out.

Ambulance Catechism. By WILLIAM ROXBURGH, M.B., C.M.Glasg. Glasgow: G. A. H. Douglas and Co. 1900. Pp. 127. Price 1*s.* 6*d.*—This little work is business-like and to the point. It asks a long series of questions and gives the answers. There are no "padding" and no preface, two admirable omissions. It contains an index—a valuable addition, especially for rapid reference in emergencies. It is intended as much for practical use as a help in preparing for examinations.

JOURNALS AND MAGAZINES.

The *Medical Magazine* for January, 1901, contains a Contribution to the Study of the Intestinal Form of Influenza by Dr. Augustine Carducci of Rome, and translated by Dr. A. C. Miller. Six cases are detailed in which, after an initial attack of a few days, the patients for a month experienced an unusual course of illness. After the first three or four days, in which the symptoms were characteristic of influenza as it is most commonly seen and yielded to the usual remedies, the temperature rose again and for the next three or four weeks was raised daily to 38° C. for more than half the 24 hours, falling to normal about 5 P.M. and remaining so for some hours. No symptoms accompanied this febrile state, and we think that Dr. Carducci has by no means conclusively shown that the origin of the fever was in the intestinal tract. Judging merely from an account of the cases we should prefer to regard them as instances of the central disorder that we know is a common result of the influenza poison. Mr. J. Foster Palmer continues his learned and attractive articles on Modern Epidemics, dealing in this number with typhoid fever. In discussing the etiology of the disease Mr. Palmer makes some shrewd and very *à propos* remarks as to the difficulty of distinguishing between air- and water-borne infection when what is primarily water-borne becomes practically an air infection through the medium of soil-water evaporation. Mr. Palmer offers consolation to all classes of inhabitants in the reflection that if country dwellers enjoy the cleanest air the cleanest water is supplied to towns. This is, of course, through the deficiencies of drainage in the scattered dwellings of country districts. Mr. A. R. Whiteway writes upon imprisonment, contending for reclamation as the prime object rather than punishment, for greater utilisation of convict labour, and, what is of particular moment to medical readers, for consulting physicians in connexion with prisons, and, generally speaking, for more thorough and expert medical investigation of misdemeanants. The articles on Some Disorders of Menstruation are concluded. The discussion of the cause of amenorrhœa wanders freely into hypothesis. Few will follow the writer to the conclusion that amenorrhœa often results from interference with uterine nerve-supply due to the occurrence in childhood of "conflagrations in the regions of the tubes and broad ligaments." Practitioners, happily, are not familiar with frequent evidence in childhood of "conflagrations" in these parts. The public health section of the magazine presents some interesting conclusions upon vaccination gathered from Dr. Arthur Reynolds's Chicago Health Report. The opinions are

arrived at, from a wide experience, that vaccination immunises if used not later than three days after exposure to infection, also that a greater degree of immunity is conferred by daily repetition of the vaccination, and that this repetition should be practised until the first vaccination shows evidence of taking, which is usually on the fourth day. The foreign section includes a remarkable piece of advice from a German authority to the effect that for the sake of the nursing of future generations "marriageable men should swear to marry only girls with full bosoms." We do not see why marriageable men should be recommended to swear, nor are we prepared to admit that the "full bosom" is necessarily that from which a good milk-supply will be forthcoming.

The December issue of the *Veterinarian* is full of original and interesting articles. Mr. Alexander Meek, M.Sc., contributes the result of a study into the "Growth of Farm Ungulates," approaching the subject in the present chapters from the external sexual characteristics, and particularly drawing attention to the differences brought about by the operation of castration in the male or female. Professor Mettam records some clinical observations on echinococcosis in the horse and on carcinoma of the dog. The article on the Breeds of Dairy Cattle by Mr. Alford of the American Bureau of Animal Industry is continued and well illustrated. We regret to see in the obituary notice the name of Professor Williams, F.R.C.V.S., F.R.S. Edin., who has been for many years the energetic Principal of the New Veterinary College; his loss will be deeply felt by the veterinary profession and by agriculturists, amongst whom his name was widely known. "Science Notes" and "The Month's Progress" contain short summaries of work done recently in the scientific world and conclude the best number the *Veterinarian* has produced during the past year.

Knowledge for January, 1901, maintains its usual high standard. The question of the size of ocean waves is dealt with by Mr. Vaughan Cornish, and Photography in Natural Colours with an Ordinary Camera is the subject of an article by Mr. H. Snowden Ward. Natural history and astronomy have also a prominent place in this number. Perhaps the most interesting article is that by Mr. R. Lydekker on Monkey Hand Prints. A clue to the pattern formed in the palm seems, he says, "to be afforded somewhat strangely by the tails of such of the South American monkeys as are endowed with prehensile power in these appendages, confirmatory evidence being likewise afforded by the prehensile tails of the American opossums and tree-porcupines as well as by those of the Australian phalangers. In all these animals the naked grasping portion of the tail, which is situated at the extremity, is covered with papillary ridges and grooves precisely similar to those on the hands and feet of monkeys but invariably arranged in simple transverse lines across the tail so that in the act of grasping they would be parallel to the long axis of the branch around which the tail is coiled. Clearly these papillary ridges are primarily connected with the grasping power."

The *Leisure Hour* in its January issue contains an interesting appreciation of the work of the late Prebendary Harry Jones with regard to open spaces. The Rev. Harry Jones was well known by name to many of our readers as a strong and sensible man. He took an active interest in the Metropolitan Hospital Sunday Fund and in all social, sanitary, and municipal questions. In the treatment of the latter he was eminently sensible. He once wrote: "That which is good is of God, though it be but the sweetening of a drain," and the phrase exhibits the man exactly. As an example of his practical manner of watching the sanitary well-being of his spiritual charges, we quote the following:—

"A deputation came from the lower part of the parish to complain of certain evil smells proceeding from the gas-works there. I personally condoled with these complainants, but, somehow, their representations were ignored as groundless. The premises were inspected by officials and pronounced to be free from the nuisance objected to. I was sure that these gentlemen had gone at a wrong time, since the offensive smells were created at night. The sufferers brought an action against the gas company which was brought into court. Jessell was the judge, Henry James and Chitty were there ready to devour the witnesses for the prosecution who spoke to the nuisance and I shall not forget their look when I (to the surprise of the audience) was put into the witness-box and was able to say that I had spent the best part of one night squatting on the roof of a public-house which overlooked the gas premises and with my own eyes had seen the opening of the doors of the furnaces from which the bad odour had issued. We won, and I shook hands with those members of the vestry who were present and had taken the side of the company. They half enjoyed learning (for the first time) about the secret nocturnal session of their rector."

Clergymen of the stamp of Prebendary Harry Jones do much to make the Church of England a power in the land. We wonder that there is not more eagerness to prefer them to important ecclesiastical positions. "The Medical Profession for Women," with illustrations, is another article of interest in the same magazine.

New Inventions.

A NEW SYSTEM OF SEWER VENTILATION.

OUR attention has been drawn to a new system of sewer ventilation which appears to us to have the merit of simplicity and easy adaptation whilst being effectual in reducing to a minimum the noxious characteristics of sewer emanations. As is well known, sewer ventilation is on all sides a source of offence and perhaps of disease, but sewer ventilation must be provided in some way or other. At present the ventilation of sewers is allowed to take place in a very haphazard way by constructing openings to the sewer in the road. The degree of offence thus caused requires no further description. Sewer-air is characterised by a sickening smell which all instinctively avoid. Attempts have been made, and with some success, to overcome the nuisance caused by level road ventilators by constructing shafts. Although shafts remove the objection to the level ventilators and allow sewer-air to escape at some distance above breathing level, yet obviously the air is still poisoned. A number of devices have been suggested for purifying sewer-air, but most of them have proved impracticable. Messrs. Stone and Co. of Deptford, S.E., have devised an apparatus which can be placed in any convenient position in the upper part of the sewer to be ventilated. The purification is effected in the first place by the use of an injector the action of which depends upon a small jet of water delivered from the water main. Sewer-air with a quantity of fresh air is then drawn by injection action into the apparatus and thoroughly mixed. The mixture of sewer-air and air is then passed through a quantity of water maintained by the same jet at a given level in a tank and therein thoroughly scrubbed or washed. The overflow runs away into a flushing tank, where it can be used for flushing the sewers, or it can be allowed to run direct into the sewer. So satisfactorily is the purification effected that both bacteriological and chemical examination have shown that the sewer-air is in this way freed from its germs and from its offensive constituents. It is stated that 10,000 cubic feet of noxious gas can be drawn from the sewer thoroughly purified and then passed into the outside atmosphere at a cost of water consumed of about 1*s.* 6*d.* It is further said that the apparatus has given excellent results with what have hitherto proved to be most troublesome and offensive sewers in certain districts of London. As we have said, the bacteriological and chemical results of examination were satisfactory, but we should like to have learned of its efficiency also having been tested by observing the effects of the treated

sewer-air upon animal life. In a classic experiment it was shown that when rats which had been respiring sewer-air were inoculated with cultures of the typhoid organism they rapidly succumbed to typhoid fever, whereas the rats kept in the open survived the effects of the poison introduced. There can be little doubt that sewer-air predisposes the human subject to sickness and disease, and any means which can be found which will destroy its toxicity will undoubtedly remove a frequent source of sickness and materially reduce a factor in the mortality returns.

SOUTHALL'S MILK STERILISER.

THERE is a distinctly new feature in regard to the method of this milk steriliser, and while the apparatus is effectual for the purpose it requires a minimum of attention. The steriliser consists of a metal container into which is placed a small quantity of water. A perforated metal shelf with its concave side downward is placed in the water and serves to support the bottle of milk. The bottle is provided with a lever stopper. All that is necessary to be done is to fill a metal cup with spirit and place it under the container after lighting the wick. The cup holds exactly the amount of spirit sufficing for the sterilisation, which takes about an hour to be complete. The same cup also holds the requisite amount of water. The apparatus is then left to itself. After an hour it will be found that the supply of spirit has been consumed and the temperature of the milk throughout will be about 160° F. The apparatus, in a word, provides for a kind of steam jacket round the bottle of milk, the quantity of spirit directed to be used being exactly adjusted for the attainment of this temperature and for the sterilisation of the milk. The apparatus is convenient, simple, and effective. It is made by Southall Brothers and Barclay, Limited, Manufacturing Chemists, Birmingham.

THE BATTLE OF THE CLUBS.

THE NEWCASTLE MEDICAL UNION AND THE MINERS.

THE Northumberland miners are admirably organised, not merely for trade-union purposes, but also for coöperative and political purposes. Miners have shown their strength by returning two of their own class to Parliament, Mr. John Wilson, the Member for Mid-Durham, and Mr. Charles Fenwick, the Member for the Wansbeck Division of Northumberland. No one personally acquainted with these representatives of the working miners can do otherwise than render homage to their integrity and their ability. It is necessary to take into account such salient facts as these before the more recent, and we fear less disciplined, organisations of the medical profession enter upon a struggle against the trade union of the Northumberland miners. The Newcastle papers announced that the Newcastle Medical Union has unanimously decided that the present rate of pay of the colliery surgeons working under the contract system is insufficient. They demand an increase of 50 per cent.—namely, 9*d*. instead of 6*d*. per fortnight. Undoubtedly, of all miners those of Northumberland are the most fortunate. In no other coal-fields are the wages so high and the hours of labour so short. The ideal of the eight hours' day has been surpassed, for the Northumberland miners generally work only seven hours a day. It is true that there is a dark side to this bright picture, as the lads or youths who prepare the work for the men remain in the mines for a longer time. But in spite of this drawback, if any class of miners can afford to pay their medical advisers a higher tariff than usual it is the miners of Northumberland. Indeed, this seems to be recognised by at least a part of the miners themselves. The colliers engaged along the Tyne banks, at the Montagu Pit, and in the pits in the neighbourhood of Lemington have accepted the terms proposed and granted the increase. Those of Prudhoe and neighbourhood are still considering the matter, but it seems as if a struggle may arise in the other districts. The Eden Colliery, Leadgate, and the Busty Pit hands of the Consett Iron Company and all miners connected with three other pits have already decided to refuse to accede to the demands. Nevertheless, the Medical Union has served notices on all he miners, and the medical practitioners have declared that they will cease to give their services under the contract system unless the increase is granted. This, therefore, may lead to a strike on the part of the colliery surgeons. We hope, however, that such an extreme course may be avoided. In the face of an undisciplined, unruly crowd a strike is sometimes necessary, for there are then no means of arguing the matter out. In the present case the miners are so well organised and are represented by such able men that it should be possible to negotiate, and this in a satisfactory manner. The miners have themselves done so much by organisation to improve their position, that they must of necessity sympathise with the efforts made by the members of the medical profession to follow their example. It is said that imitation is the sincerest form of flattery, and therefore there should be a fellow feeling between the Medical Union and the Miners' Union, and they should be able to come to terms in a friendly spirit. As this has been already done in some districts we sincerely hope that this good example will be followed in other parts of the county.

THE SPRINGBURN (GLASGOW) RECHABITES AND THEIR MEDICAL OFFICER.

Dr. J. A. Wilson of Springburn is entitled to the sympathy of the entire medical profession. He is a victim to the abuses which we have so often and for so long denounced. For 15 years he has been the medical officer of the Rechabites. At Springburn there is an adult tent and also a juvenile tent. In 1899 he had to make 450 visits to the members of the adult tent at their own homes within a radius of three miles. He had further to give 803 consultations in his surgery and to supply 530 bottles of medicine. In 1898 there was a greater amount of sickness, involving 578 visits, 721 consultations, and 714 bottles of medicine. Taking the last and most favourable year, Dr. Wilson received only about £65 for his services. At the ordinary rates charged in the district he should have received £120. The members of other societies in this neighbourhood pay 4*s*. a year, and the tramway servants pay 5*s*. ; the Rechabites, however, only pay 2*s*. 6*d*. For their juvenile tent they only allow a halfpenny a week, or 2*s*. 2*d*. a year ; and as there is no examination on admission sick and weakly children are enrolled. Dr. Wilson appealed to the Rechabites asking that the subscription paid by the adults should be raised to 4*s*., that the children should be examined before admittance, and that the subscription should also be increased. The Rechabites replied that they would allow the children to be examined before admission, but would not increase the subscription paid for them nor make any allowance for the time and trouble of examining them. As for the adults, they consented to raise the fee from 2*s*. 6*d*. to 3*s*. per annum, and this was the only concession made. Dr. Wilson finds that on an average each adult member suffers one week's illness per annum, and even 3*s*. for one week's medical attendance is a very meagre remuneration. Nevertheless, he consented to accept this if the pay for children was also raised to 3*s*. or if the children's tent was given up. All the medical practitioners in the neighbourhood were informed as to the details of these negotiations, and with one exception they loyally supported Dr. Wilson, refusing to become candidates for his post if he gave it up. Unfortunately there was a weaker vessel found and he consented to do the work at the conditions laid down by the Rechabites. If he is severely ostracised by the local medical profession he will not be able to complain. It is time practitioners should be made to feel that it is a breach of trust to their fellows thus to undersell a member of the profession. If medical practitioners tamely acquiesce in such unfair competition there is no reason why it should stop, and the abuses will increase and the position will drift from bad to worse. Cannot the medical practitioners of Springburn agree to form a medical union to be federated ultimately with other similar unions? Isolated efforts, however gallantly made, are predestined to failure. There is no strength except in union.

HABITUAL DRUNKARDS.—The want of more provision for habitual drunkards under the Inebriates Act of 1898 is obvious. The home provided some time since by the London County Council for women who are committed for three years accommodates only 100 persons. It is to be enlarged and adapted for 80 more persons at a cost of £20,000.

THE LANCET.

LONDON: SATURDAY, JANUARY 12, 1901.

"Let us now Praise Famous Men."

IN another column will be found an account of a scheme for raising a memorial in the form of a statue to one whose name is probably unknown to the majority of the inhabitants of these islands—namely, WILLIAM GILBERT. Born in 1540 he was the son of the Recorder of Colchester, and having graduated M.D. of the University of Cambridge he became physician to "that bright occidental star," Queen ELIZABETH, and successively censor, treasurer, and president of the Royal College of Physicians of London. By his great work "De Magnete, Magneticisque Corporibus, et de Magno Magnete Tellure, Physiologia Nova," he laid the foundations of the science of magneto-electricity which was in after years to bear such fruit at the hands of OERSTED and FARADAY. And now some 300 years after his death his medical brethren in Colchester are about to erect a statue to his memory, a movement which redounds greatly to their credit.

We congratulate the medical men of Colchester upon their desire to do honour to their great townsman, while the incident may surely give us all cause for serious thought when we consider how very few memorials, whether statues, medallions, or pictures, of our great scientific heroes are to be found in this country. Take the metropolis for example. There are statues of generals and admirals, of statesmen and political economists, of kings and queens, but in the city which has commemorated in statuary such examples of royalty as JAMES II. and GEORGE IV. there is no statue to HUNTER. DARWIN, OWEN, and HUXLEY live in marble or bronze in the Natural History Museum, and though few, comparatively speaking, see them there the site is an apt one. JENNER has his statue at Kensington-gardens; once it stood in Trafalgar-square, but apparently without a word of protest it was moved to a secluded glade in the west of town. The name of HARVEY lives for ever in medical memories, but there is no public monument in London to him, and the only existing authentic portrait, a picture attributed to CORNELIUS JANSEN, has never been seen, as far as we know, outside the walls of the Royal College of Physicians of London. The Harvey Grammar School in Folkestone is not a foundation in memory of the discoverer of the circulation of the blood, but was founded by his brother, Sir ELIAB HARVEY, who endowed the local charity for tanning nets and sails with "cutch"—namely, catechu. The works of our great medical men are, it is true, commemorated by means of official lectures, but these do not impress the public mind. HUNTER is probably better known to the majority of average persons than any other man of science, owing to the splendid picture of him by REYNOLDS, and we doubt whether the face of another medical man of all the famous British physicians and surgeons would be in the least recognised by the public.

Pictures and statues are, as was said long ago, the books of the uneducated, and our profession loses in the popular eye by having no objective reminders of the good done by our leaders. Not one of our hospitals in the metropolis is dedicated to the memory of a great physician or surgeon. The French have their Trousseau Hospital, but our Harvey or Sydenham hospital is still to be built. Physicians and surgeons may have desired no fame while they lived. In many instances they certainly did not receive it, but rather blame and ignominy. Even after death they have in some instances—as, for example, that of Sir THOMAS BROWNE—not been allowed to rest quietly in their graves. The commencement of a new century might well be the starting point for erecting memorials to some of our notable scientific men, not in museums, but in the street or the square. New hospitals when founded should bear the names of famous medical men, in association, may be, with that of the founder. New streets are about to be cut between the Strand and Holborn and in other prominent parts of London. It would be an admirable movement on the part of the medical profession to raise a fund for the erection of one or two statues to our neglected chieftains, and as every item of the body politic profits by the work done by our fathers in science we think that the public would follow suit. In the provinces the example of Colchester can be followed, and the medical men of any locality which once gave birth or nurture to a medical hero will deserve well of their profession if they make a move to keep that hero's memory green.

The Buildings of the New Royal Infirmary at Glasgow.

THE managers of the Royal Infirmary at Glasgow have decided to celebrate HER MAJESTY'S long and prosperous reign by rebuilding the Royal Infirmary. No more fitting method of honouring the memorable era of QUEEN VICTORIA'S reign could have been devised or one more likely to give pleasure to the gracious Sovereign of our islands; and yet we have heard in several quarters that what the Jubilee Committee—the body to whom the carrying out of the scheme has been committed—propose to do runs a great chance of being unsatisfactory in many directions. Several correspondents have warned us that the proper preliminary steps to secure a good design for the rebuilding of the Royal Infirmary have not been taken by the Jubilee Committee, so that it is not certain that the public of Glasgow will obtain the best article for their money. It may appear too late in the day to say a word of protest, as a design for the new building has now been definitely accepted by the Jubilee Committee and a sketch of it has been reproduced in the *Glasgow Herald*. But on the chance of the contract not having been signed and sealed and that there may be yet time for the Jubilee Committee to reconsider the course they have taken, we say these few words. They must not be regarded as a criticism of the design which the Jubilee Committee have

chosen, but only of the methods by which they have set about making their choice.

The Jubilee Committee appear not to have invited tenders publicly but to have asked certain gentlemen to send in designs for the new building. At the same time they obtained an assessor, with distinct qualifications for the office, to advise them as to what plan should be chosen. The first proceeding was unsatisfactory, for there was no guarantee that all the persons invited were particularly fitted to build an infirmary. Of the 10 gentlemen or firms from whom an architectural design was requested three reside in London, two in Edinburgh, and five in Glasgow, and while all have claims to be considered first-class architects their names are not equally well known as specialists in hospital work. As the committee, however, themselves submitted plans to the architects they may have considered too much special knowledge unnecessary. The second proceeding, the enlisting of the services of an assessor, is only a good one if they follow his advice. This the committee have not done. Mr. R. ROWLAND ANDERSON was the assessor and his report was published in the *Glasgow Herald* of Jan. 3rd, 1901. Out of the 10 designs it appears that he set aside four in a preferred class. Of these he selected one, bringing to a focus his opinion of the relative merits of the designs by considering among other things the following practical points: the use that it was proposed to make of the site, the amount of sunlight the buildings would receive, and the architectural treatment of the building as a commemorative memorial of the Queen's Diamond Jubilee. The Jubilee Committee completely rejected their assessor's advice and chose not the design that he placed first, nor even one of the four on his selected list, but a fifth of which in his report he only remarks that "it closely follows the committee's plans."

We do not wish to appear ungracious to the Jubilee Committee, who no doubt have been at trouble and pains for the good of the community according to their lights, and who are, we believe, responsible, directly or indirectly, for a large proportion of the money raised for the new hospital. But we would ask them to consider whether they are wise in jeopardising the value of the infirmary by not taking every possible preliminary step to see that what they are about to build is exactly what is wanted—that it is both the best and the cheapest that can be got for the money. In the face of the fact that they have neglected the advice of the assessor, they should set themselves right with the public for whom they are working. They should obtain from their medical staff an opinion upon the design of the new hospital which they have accepted and they should then make every attempt to modify the design according to the accurate knowledge of the men who will have to do their scientific work within the walls of the building. We are glad to learn that the committee intend to publish the designs of the unsuccessful competitors side by side with the design which has met with their approval, and it would be well that the estimated cost of each building should be appended to the designs. The cheapest building is not necessarily the best, but if the Jubilee Committee can demonstrate in the way we suggest that they have selected a plan with reasonable regard for economy and presenting no shortcomings from the medical point of view they will have a very good answer to any criticism of their action. But if it should turn out that they have approved a design which in the eyes of practical builders does not make the best use of the available space, which is not the one chosen for them by their expert adviser, which has no special economy to recommend it, and which their medical staff think might be improved upon, sooner or later the city of Glasgow may hold them responsible for any shortcomings discovered in the new infirmary.

The Enfield Isolation Hospital.

THERE are many duties, both statutory and moral, which devolve nowadays upon a district council, and it will perhaps be generally accepted that one of the most responsible duties thus devolving is provision for the isolation of the infectious sick. Primarily, such isolation has for its object the protection of the public health, but the actual treatment of the sick cannot by any means be regarded as a secondary matter. Inasmuch as, at least, moral suasion is often exercised by the officers of the sanitary authority with the view of inducing parents to allow their children to be sent to the isolation hospital, the accommodation provided at such a hospital should be in every sense satisfactory. Above all, perhaps, it is necessary that such an institution should possess the confidence of the public for which it caters, for without this confidence the hospital cannot prove a success. It is desirable that each patient who leaves the wards of the hospital shall be so mentally constituted in regard to the institution that he shall look back to his sojourn there with pleasure and regard the staff as some of his best friends.

We therefore regret to see that the management of the Enfield Isolation Hospital has laid itself open to criticism in the local press. Confidence in its administration is likely to be shaken and its public utility diminished. The institution in question has accommodation, it appears, for some 80 patients and the average number of patients has been, we are informed, about 50. Scarlet fever, diphtheria, and enteric fever are treated therein, but there is as yet no resident medical officer, the patients being attended by the medical officer of health, who engages in private practice and who resides some three miles distant from the hospital. He is in telephonic communication with the institution and can, it is alleged, reach it in about 20 minutes—if he be at home when the request for his attendance arrives. If he is out he has, we gather, arranged with one of his colleagues in the town to make the necessary visit of urgency. It is, of course, understood that the medical officer of health visits the hospital at least once daily. Critics of the hospital regard this arrangement as unsatisfactory, and they point to a death-rate of 25 per cent. among the diphtheria patients in justification. This percentage refers to 12 deaths from diphtheria, and it is alleged that several of these were moribund on arrival —a condition of affairs which we ourselves have often witnessed at hospitals considerably larger than the one with which we are now dealing. It is, however, the fact of diphtheritic patients being admitted into the Enfield

Isolation Hospital which makes us unhesitatingly agree with those who advocate the appointment of a resident medical officer. In our view, if there is no such officer, cases *in extremis* and requiring immediate tracheotomy must not be sent into the hospital. Antitoxin will, we know, do much when used early in the disease, but it is not of such great value later when it is reasonable to assume that the medical practitioner has applied the remedy and that it has already failed in its effect. We cannot decide between the rival statements in connexion with the Enfield Isolation Hospital, but we are in a position to affirm that the practice of sending in patients for operation is by no means unknown to us, and all hospitals which take in diphtheritic patients should, in our view, provide for such emergencies. We are, of course, perfectly aware that the children of the poor have not always a medical man at their immediate call —nor, indeed, have the children of the rich; and it is clear that the provisions for obtaining medical aid at the Enfield Isolation Hospital are far better than those possessed by many of those who are likely to become inmates of the institution. Telephonic communication is as yet by no means common between patients and their medical adviser, and the family medical man may obviously be absent when a message arrives. These things are alleged in defence of the arrangement by which telephonic communication with the medical officer of health takes the place of the services of a resident medical officer, but the conditions instanced are not quite parallel. When as many as 50 patients, some of whom are suffering from diphtheria, are gathered together in an institution to which people are often induced to go, a resident medical officer should, we think, always be appointed.

Other allegations made against the Enfield Isolation Hospital are, for instance, that no nurse is despatched with the ambulance which brings the patients from their homes, and that the patients, when discharged, have perforce to reach their homes as best they may. Both these are matters of detail which may well be considered by the management, but in regard to the ambulance, which, by the way, is a modern and well-constructed one, an attendant always appears to accompany it, while in regard to the latter point, that of discharge, the same allegation applies to the hospitals of the Metropolitan Asylums Board. As a general rule, patients when discharged from a fever hospital are quite capable of reaching their homes without danger or discomfort, and it has to be remembered that they have probably been much in the open air during their sojourn at the institution. Moreover, in rural districts during inclement weather the exercise of a little common sense in postponing, where necessary, the discharge, should go far to meet the difficulty raised, and in the case of very young children or children in arms, some suitable provision for traversing long distances should naturally be made. As regards the future, the hospital committee have asked the medical practitioners of the district to indicate upon the certificate of notification whether or not the patient is in a suitable condition to be removed to hospital, and in furnishing this information regard will doubtless be had to the accommodation provided. This seems to us to be a very reasonable request, and it is to be hoped that there will be no difficulty in complying with it. Yet another cause of complaint is that parents are only informed of the condition of the sick in the event of their becoming seriously ill, but such an inconvenience can easily be remedied by placing the hospital in telephonic communication with the district offices, and perhaps other convenient centres, in order that the not unnatural anxiety of parents may be allayed without application to the hospital itself. We suggest to the management of the Enfield Isolation Hospital the desirability, in the interests of all concerned, of taking into serious consideration the points here referred to.

Annotations.

"Ne quid nimis."

DEATH FROM SUFFOCATION AFTER A DENTAL OPERATION.

A PARAGRAPH of a distinctly misleading nature has appeared in several lay contemporaries which states that a patient at Newport, Mon., died from the effects of "laughing gas" during a dental operation. The facts of the deplorable case, of which we gave a brief account last week, are, we believe, correctly stated as follows. The patient, a healthy miner, went to a dentist's rooms to have 11 teeth extracted under an anæsthetic. The dentist, a Licentiate in Dental Surgery of Ireland, administered nitrous oxide and ether, a nurse, but no medical man, being present. The removal of the teeth was successfully accomplished and sponges without attachment outside the mouth were used to press on the gums to check the hæmorrhage. The deceased sat listlessly in the dental chair for two or three minutes after the completion of the operation, then sprang to his feet, drew in a deep breath, and gasped for air. As signs of asphyxia were plainly evident the dentist felt digitally for any obstruction in the air-passages and finding none commenced artificial respiration. A medical man was sent for and on his prompt attendance he found the patient deeply cyanosed, lying upon the floor, and the dentist performing artificial respiration. The pupils were widely dilated and life appeared to be extinct. After pulling forward the tongue and again employing artificial respiration, the medical man examined the back of the throat with his finger and felt externally with the view of discovering if any foreign body was lodged in the air-passages. Remedies were used, but without effect. A necropsy was made on the following day and a sponge was found lodged below the vocal cords. The obvious lessons to be gathered from the above narrative are twofold. We have more than once urged the desirability of the presence of two qualified medical men when only a trifling operation has to be performed under an anæsthetic. It is even more necessary when the operator is a dentist not possessing a surgical qualification that a duly qualified medical man should be with him to give the anæsthetic. No man can with safety to his patient administer an anæsthetic and operate single-handed. But further, there is in every case in which an anæsthetic is given a liability to accident, and at any moment tracheotomy or some other purely surgical procedure may be required to meet emergencies arising as a result of the operation or of the anæsthetic. Is a dentist competent to deal with such emergencies? We do not mean is he legally justified in giving an anæsthetic; that is a matter beside our present contention, but we ask, is he by his education and experience able to perform in a satisfactory manner the surgical operations which may be required as a result of a sudden emergency? We submit that he is not. His armamentarium will in nine cases out of ten not contain

a set of tracheotomy instruments, and it is not in the least unlikely that he has never performed the operation. In the case of ether or chloroform certainly, and we should add in that of nitrous oxide, a dentist would be well advised if he refrained from giving the anæsthetic, and he should under no circumstances undertake so grave a matter without the aid of a surgeon. The second lesson is one of practice. As we understand the case, the man was apparently recovering from the narcosis and the sudden appearance of cyanosis with dyspnœa could point to only one cause—the occlusion of the air-passages by a foreign body. The dentist and the medical man appear to have recognised this, although the latter as he came late upon the scene was possibly put off his guard by the absence of knowledge of the course which the symptoms had run. Artificial respiration was obviously useless as no air entered the lungs, and tracheotomy was not performed. This operation might have saved the man's life if it had been done in time—that is, if the surgeon had been present from the beginning of the proceedings.

A SMOKELESS UNDERGROUND RAILWAY.

THE proposal to adopt electric traction on the Metropolitan District Railway has been thoroughly supported by the shareholders of the company, and we are not surprised, since they must feel that all prospect of income is doomed by the fact that better means of travelling underground are at hand, while the public are sick of the experience that is offered to them by the existing underground steam trains. These are exceedingly unhealthy and exceedingly dirty, and apparently the attempts that have been made at ventilation have produced no practical results. The use, therefore, of smokeless traction is the only chance, it seems to us, of making the old underground railways wholesome and of saving the enterprise from absolute financial disaster. It cannot be denied that this system is the most useful line in London, and once wipe away the reproach as to the filthy state of its tunnels and railway carriages it will undoubtedly secure a big *clientèle*. We cordially welcome the decision that electric traction is to be used, but at the same time we are curious to know how it is proposed to meet the difficulty of trains of other systems running upon the lines. Thus the Midland, the Great Northern, the London and North-Western, and the Great Western railway companies, all overground systems, have running powers on the underground railway. Would the steam-engine be detached somewhere and an electric engine be hitched on? This would, of course, mean delay.

QUACKS AND ABORTION.

AN inquest concluded at Huntingdon on Jan. 2nd shows that the trade in quack medicines which are liable to be taken by pregnant women in the hope of procuring miscarriage has not yet ceased; that newspapers are still, whether knowingly or not, the means of advertising such nostrums; and that the compounds sold are apparently capable of causing the desired effect, subject to the reservation that they must be taken in very large quantities. That the death of the person so procuring abortion upon herself is a not unlikely sequel to her temerity also stands revealed. In the Huntingdon case the facts proved at the inquest differ in no material particular from those which have been brought out in many of the inquiries that were more common before recent prosecutions, and before our articles on the subject had called attention to the danger of selling would-be abortifacients and publishing advertisements of them. The woman upon whom the inquest was held had died from acute general peritonitis following miscarriage. Before death she had admitted taking constantly for about three weeks, with the object of procuring abortion, certain pills the advertisement of which she said that she had seen in a newspaper. She had been advised to take the pills, she said, by a male relative who, having been duly cautioned by the coroner, decided not to give evidence. The pills on analysis by Dr. Thomas Stevenson were found to contain iron or steel, aloes, colocynth, apiol, and strychnine, the majority of which ingredients, it will be remembered, figured in several of the compounds analysed by us in our inquiry into "Quacks and Abortion"[1] Dr. Stevenson added in his evidence that the pills analysed by him were not such that, taken in accordance with their printed label, they would be likely to produce miscarriage, but that taken as the deceased had apparently taken them they might have that result. It is always possible that legal proceedings may follow upon such an inquiry, and we therefore withhold further comment. We note, however, that the father of the deceased seems to have reproached the medical man who was called in by her when it was too late to save her life, with not having at once informed him of the cause of her condition. The coroner, Mr. C. B. Margetts, promptly and firmly supported the medical man in the position which he had taken up, pointing out that as long as it was possible that the woman's life might be saved he was the custodian of her secret, amounting to the confession that she had committed a criminal act, and that, so far from his having any duty to communicate this to her relatives, it might have been his duty to keep it as a professional secret from the knowledge of everyone. On her death becoming imminent, the coroner added, the medical man's position changed, because it was then evident that an inquiry must take place into the causes of it; and on such an occasion, when the patient can no longer suffer by the divulging of her secret, publicity followed by the fullest inquiry makes for the public good and for the protection and warning of other women.

WHEN IS AN IMPROVEMENT NOT AN IMPROVEMENT?

A CORRESPONDENT writes from Bournemouth:—"Public opinion in this place has lately been greatly excited over an 'Omnibus' Bill which the corporation proposes to introduce during the next session of Parliament. Much of it is only of local interest, as it deals with such matters as electric tramways, widening roads, &c.; but one clause is concerned with the acquisition by the corporation of a large open space, the Horseshoe Common, as a site for 'municipal and other buildings.' This proposition involves practically the destruction of one of the principal 'lungs' of the town and is therefore of the greatest interest to all those medical men who have been in the habit of sending their patients to this really delightful health resort, as I hope I may call our town although I live in it. The plot of ground, 14 acres in extent, is well known to all visitors to Bournemouth. It is in the very centre of the town and is a bit of wild moorland, surrounded by fir-trees and covered with gorse, bracken, and heather. As far as I know, no such bit of unadorned nature exists in the centre of any other town in the kingdom. By an Act of Parliament, obtained by the corporation so recently as 1897, two acres of this ground at its lower end were given up to the corporation as a site for the municipal buildings, but it was expressly stipulated that the remaining 12 acres should (for 99 years) be reserved for gardens and pleasure-grounds. '*L'appétit vient en mangeant*,' however; and it has grown so rapidly that now the corporation desires to devour the whole of the space. What may be its immediate intention is not declared, but the clause in question would

[1] THE LANCET, Dec. 10th (p. 1570), 17th (p. 1651), 24th (p. 1723), and 31st (p. 1807), 1898, and Jan. 21st (p. 182), Feb. 4th (p. 327), March 11th (p. 717) and 25th (p. 856), April 1st (p. 908), June 24th (p. 1739), July 8th (p. 111) and 15th (p. 174), and Dec. 2nd (p. 1540), 1899.

undoubtedly give it power to erect any building it pleased upon the site. Already a free library, baths and washhouses, and a terminus station for the Great Western Railway have been mentioned as possible 'improvements' of the common. Numerous petitions and memorials on the subject have been addressed to the council and to the ground landowner, and have been signed by the most prominent of the medical practitioners here, but, so far, they deal chiefly with the burdens that will be charged upon the rates under the new scheme. Surely the question of the injury that will be inflicted upon the public health of the town is more important, while the lowering of the deservedly high reputation of Bournemouth in the eyes of our medical colleagues throughout the kingdom may, directly and indirectly, cost the community more than is implied in the raising of rates." Thus our correspondent, and we have only to say that we agree with him cordially. Every municipality should endeavour to provide itself with good premises, for it is expected to be as far as possible an example of the cleanliness and order which it exists to maintain. But a municipality should not house itself well at the expense of the best interests of the inhabitants of the place under its charge, and the corporation of Bournemouth will have to make out a case of absolute necessity if it wishes to justify the proposed destruction of Horseshoe Common. A distinguishing feature in a place with the reputation of Bournemouth should not be lightly obliterated, and we trust that organised opposition to the scheme of the corporation will be set on foot. If in the face of this resistance the corporation can show that its scheme is necessary for the well-being of Bournemouth it will be justified in proceeding despite of sentiment; otherwise, however fine the buildings which it erects, it will have perpetrated an act of Vandalism.

EPIDEMICS OF SMALL-POX.

OUR sanitary laws, including the provision of a system for the notification of the chief infectious diseases and for their isolation, have the disadvantage of throwing us somewhat off our guard as to the risks we run. This is especially so in the case of small-pox, which is no sooner detected than it is isolated severely and all persons exposed to the infection are isolated too and revaccinated into the bargain. But in spite of all such laws we are reminded that small-pox is still small-pox, and that it will sooner or later assert itself in the absence of efficient vaccination and revaccination on an epidemic scale. Our Paris correspondent told us in THE LANCET of Nov. 24th of a recrudescence of small-pox in that city, where in ordinary times, owing to the vaccination laws being obligatory, there are very few cases. In 1899 there were only four deaths. In 1900 came the Exhibition and an influx of foreigners. From Jan. 1st to the end of May there were 15 deaths, from June 1st to Nov. 11th there were 100 deaths, and our correspondent reported in THE LANCET of Dec. 22nd that 17 deaths had occurred in the previous week—as high a rate as any recorded since the beginning of the epidemic, and this in spite of vigorous measures of the police for promoting free revaccination and the opening of stations at all hospitals and at most of the *mairies*, which were thronged all day long. Again, the *Medical Record* of New York of Dec. 8th states that a nest of small-pox patients had been discovered by the Board of Health in West Sixty-ninth-street. Between 30 and 40 patients were found and removed to hospital. Our contemporary adds what, of course, we expect to read, that the result of the discovery and its publication in the papers has been a vaccination boom of no mean proportions. The publication of such facts may serve to restore the reason of some people and their power to form a fair estimate of the situation of this country with its ever-accumulating millions of unvaccinated people and its constant contact with New York and Paris. No system of sanitary police yet discovered can be relied on to protect unvaccinated persons or persons who have not undergone proper revaccination. Cases of small-pox occur unexpectedly. The sufferers move about in a state of undefined and perhaps unsuspected malaise for days, infecting others as they go along, till, as in New York, a nest of cases has accumulated. We should be failing in our duty if we did not give editorial prominence to such risks. But in the present mood of English intelligence on the subject we do not expect that anything short of an epidemic will drive people to the vaccinator. Then they will run with undignified haste when it may be too late. In the meantime all fair and sensible people will see that the epidemics we refer to, and all epidemics of small-pox, are only controlled by revaccination efficiently performed.

A MODIFICATION IN OPHTHALMIC TEST-TYPES.

DR. E. PRAUN of Darmstadt has proposed an ingenious substitute for the types generally in use for the purpose of testing the sight.[1] He observed that some school-children and also a railway engine-driver whom he had occasion to examine succeeded in learning the ordinary test-types by heart, so that they could name the letters without being able to see them distinctly, and thereby made their vision appear to be better than it really was. In order to counteract this artifice Dr. Praun suggests that the use of letters of the alphabet as test-types should be discontinued and substitutes for them two thick parallel black lines of unequal length joined together by their ends, some of them at an angle of 45° and others at a right angle forming L. These radiating pairs of lines he regards as the hands of a clock, and his sheet of test-types consists of 47 such pairs of lines of different sizes placed within circles, arranged in two squares of 9 and 36 figures respectively and 2 separate figures. Each of these squares is mounted on cardboard and rotated into different positions, so that the most retentive memory would be unable to remember all the possible combinations and the reality of the test would be assured.

THE PSYCHOSES OF ENTERIC FEVER.

IN a recent issue of the *Münchener Medicinische Wochenschrift* (Nov. 20th, 1900) Dr. Deiters gives an account of his observations made at the asylum at Andernack on the various psychoses occurring in typhoid fever. These psychoses he divides—following the lines laid down by Kraepelin—into three groups—viz., first, the initial delirium attributable to the specific toxins or ferments circulating in the patient's blood and acting on the brain; secondly, the psychical disturbance of the pyrexial period attributable to the action of toxins and of the high temperature; and, thirdly, the post-febrile psychoses associated with the stage of convalescence and the condition of general bodily and cerebral exhaustion during this stage. In illustration of the initial delirium he records two cases occurring in children (one male and one female) of neurotic parents, the symptoms being those of acute mental confusion (Verwirrtheit) developing on a basis of hallucinations. This form of mental confusion constitutes the culminating point of a series of prodromal symptoms, the chief of which are restlessness, dulness, and apathy, and wet and dirty habits, the total duration of these symptoms being about 10 days. The pyrexial period then sets in and is marked by the acute psychical disturbance mentioned. The distinctive clinical symptoms of enteric fever—viz., rose spots on the abdomen and chest, splenic enlargement and tenderness,

[1] Tafel zur Bestimmung der Sehschärfe mittelst der Uhr. (Sheet of Diagrams for the Estimation of the Sharpness of Vision, arranged on the Principle of a Clock-face.) Wiesbaden: J. F. Bergmann. Glasgow: F. Bauermeister. Price 1 mark 20 pfennig.

and Widal's reaction with the blood—were found in one of the patients, a male, while the diazo-reaction of the urine was established in the case of the female patient. The latter case ended fatally and a necropsy revealed typical enteric ulcers in Peyer's patches in the large intestine, and right-sided fibrinous pleurisy. Dr. Deiters comments on the clinical importance of recognising that such delirious manifestations occurring in a neurotic child at the onset of fever should make the physician suspect typhoid fever, and considers that treatment in bed should at once be adopted in view of the possible gravity of the case.

THE ASTLEY COOPER PRIZE.

As will be seen by an advertisement in our last issue, the next triennial prize of £300, under the will of the late Sir Astley P. Cooper, Bart., will be awarded to the author of the best essay or treatise on "The Pathology of Carcinoma and the Distribution and Frequency of the Secondary Deposits, corresponding to the Various Primary Growths." The competition is open to everyone except the staffs of Guy's and St. Thomas's Hospitals and their relations, but the essay must not be the production of two or more authors, and essays, written in English, must be sent to Guy's Hospital, addressed to the physicians and surgeons, on or before Jan. 1st, 1904. It is possible that the successful essay will be printed in the Guy's Hospital Reports, but this will in no way prevent the author from publishing it elsewhere after obtaining permission. Further particulars as to the conditions of competition and the like may be obtained on application to Dr. Newton Pitt, Guy's Hospital, London, S.E.

RADIOSCOPY OF THE MEDIASTINUM.

IN a paper[1] read at the International Congress of Electrology and Radiology, Paris, 1900, Dr. Mignon, after pointing out the difficulty of examining clinically the mediastina, divides his subject into three parts: (1) the anterior; (2) the posterior; and (3) the lateral oblique methods of examining the mediastina with the x rays. Under the first division he calls attention to the shadow cast by the thymus gland in children up to the third year. He then describes a shadow that is occasionally seen in radiographs of the adult chest situated on each side of the manubrium sterni and which extends obliquely upwards and outwards towards the axillæ and says that this shadow corresponds to the large vascular trunks. With this explanation we cannot agree. The shadow in question is found on stereoscopic examination to be outside the chest and corresponds to the anterior axillary fold. Dr. Mignon then goes on to the consideration of the heart shadow and points out that its situation, independently of pathological displacements (dexiocardia, pleurisy with effusion, &c.), is not always the same, the position being different in the standing from the recumbent position. He might have added that no two heart shadows are exactly alike. Radiographically one man might be known from another by the shadow of his heart. We quite agree with Dr. Mignon's view that the volume of the heart cannot be estimated by a screen examination only. Dr. Mignon thinks the pericardium is not visible on a screen examination, but says that in some skiagrams the observer may be able to distinguish beyond the limit of the heart shadow a lighter shadow that corresponds in position to the pericardium. We fully agree. Light streaks rather than shadows are often seen running parallel with the right and left borders of the heart, which in the dead subject, with lungs removed, clearly correspond to the borders of the pericardium. Dr. Mignon's paper is open, however, to some criticism. In discussing the position of the shadow thrown by the aortic arch and the changes under which it goes in aneurysmal dilatations Dr. Mignon makes no mention of the stereoscopic method of examination. He appears to be unacquainted with this important means of diagnosis, which has been rendered easy of application since Mr. Mackenzie Davidson invented the stereoscopic screen. In the second part of the paper Dr. Mignon deals with the examination of the posterior mediastinum and the detection of enlarged bronchial glands and aneurysms of the thoracic aorta. He maintains that the x rays are the only means of diagnosing accurately an aneurysm of this part of the aorta, which a good many clinicians will consider too sweeping a statement. For the diagnosis of abnormalities and diseases of the œsophagus Dr. Mignon recommends the swallowing of metallic balls attached to strings as preferable to the metallic sound in cases where hæmorrhage or perforation of the œsophagus is to be feared, but in our opinion the suggested manœuvre might be as dangerous as the method which it is designed to supersede. The third part is the most valuable portion of the paper: that is, the lateral oblique method of examining the mediastina. It is well known that a strictly lateral view of the chest, either with the screen or photographic plate, shows nothing very definite. Dr. Mignon's method appears to us to be a valuable one. It consists in getting an oblique view of the chest either with the screen anteriorly or posteriorly, so that we have a lateral oblique view anteriorly and posteriorly. By this method Dr. Mignon says a clear zone is seen bounded as follows: below it is limited by the convex shadow of the diaphragm, in front by the shadow of the heart, behind by the shadow of the vertebral column, which includes those of the aorta, vena cava, and œsophagus. If the aorta be the seat of an aneurysm the anterior border of this shadow is not regularly vertical. This clear zone is somewhat triangular in shape. Dr. Mignon proposes to call it the retro-cardiac triangle. By the lateral oblique method we see that the heart is not in actual contact with the anterior chest wall—a clear space is seen between them corresponding to the anterior mediastinum. Dr. Mignon claims that by this oblique method of examination pathological changes in the mediastina may be discovered which would be missed in an anterior or posterior examination only. Valuable as this method may be we still think that it is not superior to the stereoscopic method of examination, by which means we obtain the third dimension in space. Although we have found some fault, the paper is an extremely interesting one and should be read by all interested in radiography of the chest.

[1] L'Examen du Médiastin par la Radioscopie et la Radiographie, by Dr. M. Mignon (of Nice). Paris: G. Steinheil. 1900.

THE LOGIC OF A CORONER.

FROM the *Liverpool Post* of Jan. 4th we learn that on the previous day an inquest was held by the county coroner at the St. Helen's Town-hall, on the body of Mary Ann Teresa Ronchetti, aged 64 years, wife of the caretaker of St. Joseph's Roman Catholic Schools. According to her husband's statement the deceased had suffered from paralysis for 18 months. Early on Sunday, Dec. 23rd, she fell out of bed and fractured her leg. Mr. P. J. O'Keefe, who was summoned as a witness, said that he was called in to see Mrs. Ronchetti on the day of her accident and found her suffering from bronchitis, fracture of the left leg, and cardiac syncope. He ordered her removal to the Providence Hospital. In the course of the proceedings the coroner produced Mr. O'Keefe's certificate, which ascribed the woman's death primarily to apoplexy and bronchitis, and secondarily to compound fraction of the leg with cardiac syncope. On being asked whether the compound fracture had accelerated death in any degree, Mr. O'Keefe said that he scarcely thought that it had done so, and that the bronchitis alone was

sufficient to account for death. Upon this the coroner appears, according to the newspaper report, to have censured him severely, giving it as his opinion that if the fracture of the leg had nothing to do with the death it should not have been mentioned in the certificate. In vain Mr. O'Keefe explained that he had mentioned the fracture in order to comply with the instructions of the Registrar-General. "If I had not done it," he said, "I might have been in the wrong. Even though you cannot absolutely connect things with the cause of death you are bound to put them down." Upon this followed an angry altercation between the coroner and the witness. Addressing Mr. O'Keefe, the coroner is reported to have said, "You and I have differed before, and we differ again now. I did give you credit for having a logical mind, whatever else you have. I am trying to drive some logic into you," &c. We have not space to follow the coroner further in his criticisms. We would, however, remark in passing that whatever may be the qualifications that the learned coroner possesses as a teacher of logic, his arguments, as reported in the local newspaper, fail to impress us with his skill in the application of that science. We trust that on reflection the coroner will see it right to apologise for his discourteous conduct towards a medical witness who, in spite of the coroner's opinion to the contrary, appears to us to have honourably done his duty. We would remind the coroner that a compound fracture of a limb is a very serious injury, quite sufficient of itself to cause death under certain circumstances, especially in the case of a paralysed woman 64 years of age. We do not know what instructions the authorities at Somerset House may have issued in such cases, but we are convinced that if Mr. O'Keefe had omitted to state in his certificate, in addition to the primary cause of death, the fact that his patient had sustained a dangerous injury of this kind, he would have incurred a very serious responsibility for which as a practitioner of medicine he would have been justly censurable. The statement of the fact of injury could do no harm, but its suppression might conceivably have led to a miscarriage of justice.

MR. SHAW-LEFEVRE AND THE LLANDAFF COMMISSION ON THE LONDON WATER-SUPPLY.

WE had the pleasure lately to record the facts that Mr. Long, the President of the Local Government Board, has undertaken to give his immediate attention to the question of the metropolitan water-supply, and that he has publicly expressed his wish that the Metropolitan Boroughs and the extra-metropolitan Authorities, the bodies chiefly interested in this question, should give him their views as to whether it is desirable that any changes should be made in the present arrangements with regard to the water-supply, and if so should state what form these changes should take. Mr. Long's appeal has apparently displeased Mr. G. Shaw-Lefevre who, in a letter which appeared in the *Times* of Dec. 28th, makes a violent attack on the report of the Llandaff Commission—"I would suggest to the President of the Local Government Board that in the interval between this and the year 1902, when he has undertaken to introduce a Government Bill on the subject, he should appoint another Royal Commission to inquire into the scheme of the last one—a commission this time '*de lunatico inquirendo*.'" This brief citation will suffice to show the spirit in which Mr. Shaw-Lefevre's letter is written. We do not propose to deal at length with the various points raised by Mr. Shaw-Lefevre, but as he writes as an interpreter of the Llandaff report we feel it necessary to point out some mistakes into which he has fallen in regard to the matter. The mistakes are fundamental. The Llandaff Commission amongst other things were instructed to report "whether, having regard to financial considerations and to present and prospective requirements as regards water-supply in the districts within the limits of supply of the metropolitan water companies, it is desirable in the interests of the ratepayers and water consumers in those districts that the undertakings of the water companies should be acquired and managed either by one authority or by several authorities, and if so, what should be such authority or authorities." The Llandaff Commission reported that a Water Board should be appointed, that it should be a permanent body, that the members should be selected on account of their business capacity and, if possible, their knowledge of matters connected with water-supply. Mr. Lefevre complains that this scheme was not "ventilated" by the Commission. The Commission were not appointed to ventilate a scheme but to draw up a scheme. This they did. In the course of their inquiry the Commission thoroughly "ventilated" a scheme propounded by the London County Council. In their report it would not be too much to say that the Commission did not content themselves with "ventilating"; they even had the hardihood to "blow upon" the scheme of the London County Council. We have already at some length summarised the Llandaff report, and we have not scrupled to point out its weak points, but the letter of Mr. Shaw-Lefevre is unjust and ungenerous to members of the Commission. Had he been present at all the sittings of the Commission or had he carefully read the shorthand notes of the evidence we are convinced that he would not have written in the spirit of his letter to the *Times*. According to general rumour Lord Llandaff himself drew up the report, and however this may be, the lucidity and ability displayed in it are undeniable. The late Major-General Scott, the Water Examiner to the Local Government Board, was able to explain to the Commission all the intricacies and difficulties of the question, and Lord Llandaff examined the witnesses with the greatest thoroughness. On careful winnowing, much of the evidence was found not to be weighty and much of the time of the Commission was thereby wasted by witnesses. In such conditions a lazy or weak chairman might have been deceived or might have become irritable. But in the whole of this long inquiry we can recall no single instance in which Lord Llandaff administered a reproof which was not entirely deserved.

A MEDICAL TRIBUTE TO THE FATHER OF ELECTRICAL SCIENCE.

THE members of the medical profession at Colchester have combined to erect a full-length marble statue of Dr. William Gilberd (or Gilbert), the famous physician to Queen Elizabeth, whose work, "De Magnete," published in 1600, laid the foundations of electrical science. The importance of Gilberd's researches can scarcely be exaggerated. As Galileo said of him, he is "a man of enviable greatness," and the medical profession may justly hold his name and reputation in the highest possible honour. Gilberd was born in Colchester, where his father occupied the position of Recorder. He showed his regard for his native town by describing himself on the title-page of "De Magnete" as "Gulielmus Gilbertus Colcestrensis." He died in Colchester and was buried a few yards only from his birthplace, in the church of Holy Trinity, where his monument remains. The statue which is to be erected in his honour will be placed in a niche in the main façade of the new Town Hall at Colchester, a handsome building now being erected from the designs of Mr. John Belcher, A.R.A. The cost of the statue will be not less than £150, and towards this sum Mr. Henry Laver, F.S.A., the senior medical practitioner of

the town—who is acting as treasurer—has received £130, entirely contributed by the medical men of the borough or its immediate neighbourhood. The medical men of Colchester have done honour to themselves and their profession by their prompt and generous response to the appeal. issued less than a month since by Mr. Laver. As Gilberd's fame is a glory to the whole medical profession, and, indeed, to the whole English-speaking race, it is possible that there may be some of our readers who would like to help the medical men of Colchester—not a very numerous body—to secure the required total, or, still better, to obtain an even larger sum, so that a statue may be erected worthy of one of the greatest of Englishmen. This will, strange to say, be the first statue ever erected of this pioneer in scientific research, the father of the electrical science which has done so much to transform the history of the world. The stipulated minimum, £150, seems but a small sum for such a purpose, and we hope to hear that it has been exceeded.

THE REMOVAL OF SNOW FROM THE STREETS.

THE methods of removal of snow from our streets, like the problem of the prevention of fog in the metropolitan atmosphere, prove a hardy annual for discussion. The discussion, however, soon dies down as either nuisance naturally disappears, but it becomes once more active at the next serious snowfall or at the next prevalence of fog, as the case may be. It cannot be said that in regard either to fog or snowfall, in spite of all discussion, the metropolis is one jot nearer a better state of things; but we hope that the matter will not be allowed to drop, now that the thaw which set in on Wednesday has relieved our municipal authorities in London from immediate anxiety. We desire to have the questions threshed out in times of meteorological peace, so that our resistant forces may be ready when the heavens again declare war. The conditions favourable to the production of fog are, we fear, well-nigh impossible to avoid, but it seems odd that no really satisfactory way has been found for the disposal of snow in the streets. The removal of snow by cartage is at its best a slow and clumsy process, while its disposal by liquefaction, as by the addition of salt, is highly objectionable unless certain precautions be taken, although the method may be expeditious and economical. As is very generally known, it is now the duty of the sanitary authority to clean our streets and to remove refuse, the expression "street refuse" being taken to mean dust, dirt, rubbish, mud, road scrapings, ice, snow, and filth, according to the Public Health (London) Act, 1891. Formerly, each individual occupier of premises was required to keep the pavement exactly in front of his premises clean. This, however, did not refer to the roadway. Now this duty devolves upon the sanitary authority who should see that the streets are properly swept and cleansed "so far as is reasonably practicable." This rule is still in force in spite of representations that have been repeatedly made that the old rule which entailed this duty on the householder should be reverted to. In March last year a householder attempted to bring proceedings against a sanitary authority for non-compliance with this provision of the Public Health Act, but the action failed because it was tendered in the evidence on behalf of the sanitary authority that all that was "reasonably practicable" had been done. It seems to us that the words "reasonably practicable" form a sort of unlimited excuse, and thus militate against the work of the removal of snow being done with that efficiency which in the interests of comfort and health is demanded. The condition of our streets after a fall of snow is invariably a reproach to our sanitary administration. We are well aware that the expeditious disposal of snow is not an easy matter unless steps are taken to have at hand an enormous staff of labourers to shovel and sweep the accumulated snow from the streets. This, however, is not only a source of very great expense, but it is not always practicable to suddenly enlist the services of a temporary staff of scavengers for this purpose. Besides which the fall of snow may continue for a long time. Hence salting the snow has been adopted chiefly on account of the ease and rapidity of the process. The result is a chilling slush which remains to be splashed in all directions and to make every pedestrian uncomfortable. Slush at a temperature near to zero is bad alike for horse and pedestrian. Only one point appears in favour of this method, and that is that it enables the horse to gain a footing. There is some force undoubtedly in this, for it is a cruel spectacle to see horses struggling for a foothold on snow hardened by traffic or by frost. The "salting" method would seem more satisfactory if the cold, fluid, freezing mixture could be at once swept away, but as a rule the slush is left to ooze away and its ultimate dissolution is a slow process. The authorities appear to prohibit the direct discharge of this mixture into the sewers, for what reason we cannot precisely see. Surely melted snow is no worse to deal with than the fluid which carries with it the refuse of the streets, while the presence of salt in the sewers can hardly be an objection. In these days of motor-cars and steam vehicles in our streets we are surprised that no attention has been turned to constructing a steam scoop, so to speak, fitted with a receptacle for the scooped-up snow. Mud is removed from the streets by means of large revolving brushes and we do not see why a similar arrangement could not be adopted for the removal of freshly fallen snow. It may be that the fact that the removal of snow is after all only rarely required does not make it worth while to construct a machine of this kind. But the inconveniences to traffic, besides the ill-health and excessive discomfort occasioned to pedestrians, demand a more rational means of removing the snow than appears to be at present available. We do not doubt that engineers, if they would only give a little attention to the matter and were stimulated by the promise of an award, would quickly solve the problem and thus protect the health and earn the gratitude of thousands. The question arises every year and it is a disgrace to the metropolis that it has not so far been satisfactorily solved.

CREASOTE POISONING.

CREASOTE poisoning is very uncommon. In the *Intercolonial Medical Journal of Australasia* of Oct. 20th, 1900, Mr. Herbert M. Hewlett relates the following case of creasote poisoning in a child. A girl, aged three and a half years, swallowed about two drachms of creasote. Immediately she complained of abdominal pain and was given a tablespoonful of olive oil. She rapidly became unconscious. About 20 minutes afterwards, when she was seen by Mr. Hewlett, she was insensible, with pale face, cyanosed lips, shallow respiration, and imperceptible pulse. The eyes were fixed, the pupils were contracted and immobile, the extremities were cold, and the muscles were flaccid. The stomach was washed out with about two quarts of warm water. A small quantity of food was present and the washings smelt strongly of creasote. The stomach was next washed out with two pints of a strong solution of magnesium sulphate and about six ounces were left in the viscus. Strychnine, $\frac{1}{75}$th of a grain, was injected hypodermically and she was put in blankets and surrounded by hot blankets. An enema of Liebig's extract and brandy was also given. About eight minutes after emptying the stomach the colour of the lips improved and the pulse became perceptible. Ten minutes later the colour was good

and the respiration was full and regular. The pupils were still contracted but reacted to light and the extremities were warm. In a couple of hours she drank white of egg and milk but complained of pain over the stomach, which was relieved by hot fomentations. Urine passed many hours after taking the drug was dark brownish. The first motion was also dark and smelt strongly of creasote. A second sample of urine was of a watery green colour. No after-effects followed and in a couple of days the child was running about again. Creasote closely resembles carbolic acid in its action but is a weaker caustic and does not produce convulsions.

PRIMARY OVARIAN GESTATION.

IN the Annus Medicus for 1900 reference is made to Mdlle. van Tussenbroek's case of primary ovarian gestation. It is stated that Mr. Bland-Sutton was inclined to regard her specimen as a doubtful one of this condition. In fairness to Mdlle. van Tussenbroek it should be pointed out that at the last meeting of the Obstetrical Society of London, on Jan. 2nd, Mr. Bland-Sutton said that he had had an opportunity of examining the specimen itself and microscopical sections of it. Two of these sections he was able to exhibit at the meeting. An examination of them left no doubt as to the existence of chorionic villi, and he was therefore convinced that this form of ectopic gestation was possible. Those who had an opportunity of looking at the sections agreed with Mr. Bland-Sutton's views.

DEPILATION BY HIGH-TENSION ELECTRIC CURRENTS.

AT a recent meeting of the Vienna Society of Physicians Dr. Schiff and Dr. Freund reported an interesting action of high-tension currents on the skin. According to the authors, when the hairy skin is exposed for 20 minutes to the silent discharge of the negative pole of a powerful Ruhmkorff coil, such as is used for the production of the Roentgen rays, the hairs commence to fall out, the hair-bulbs become atrophied after the third exposure, and some days later the portion of the skin which had been exposed becomes perfectly bald. The hair follicles become red and inflamed after the first two exposures. These observations seem to prove that depilation can be produced by the action of high-tension currents and that the depilatory effect of exposure to the Roentgen rays may be accounted for in this way.

MYASTHENIA GRAVIS OR ASTHENIC BULBAR PARALYSIS.

DR. PAUL of Boston, in the *Boston Medical and Surgical Journal* of Dec. 20th, 1900, adds another case to the list of about 70 cases of this obscure disease[1] now known to literature. The case is that of a married woman 23 years of age. One maternal uncle was insane, and there was a neurotic tendency in the father's family. Eight months previously while performing at private theatricals, she suddenly felt weak and unable to rise from the stooping position without assistance. Eventually such acts as ascending stairs or boarding a tramcar became impossible to her unaided. Transient weakness in the arms followed, and there was difficulty in buttoning her dress or in doing embroidery and the like. Transient attacks of diplopia also occurred. On one occasion she fell while carrying her baby upstairs and slid down several steps, without, however, injuring herself. There was lack of expression in the face, and the voice was at times nasal and somewhat indistinct. Swallowing was sometimes awkward, and the neck muscles sometimes suddenly gave way so that the head required support. Mastication was not affected. On three different occasions she fell helpless on the floor, unable to move or speak, and had to be assisted up. Appetite and digestion were good, but she sometimes could not swallow and suffered from choking and cyanosis. Emotional excitement rendered her worse. The sphincters were not affected. The bulbar symptoms increased in severity and death occurred 18 months after the first symptoms. The necropsy, made by Dr. G. Magrath, revealed macroscopically nothing. The diagnosis was "myasthenia gravis," also called asthenic bulbar paralysis or Erb-Goldflam's symptom-complex. In the cases recorded there is a mortality of over 33 per cent. No explanation is offered of the etiology or pathology of the affection, though some writers have suggested that an unknown toxin of microbial origin plays the chief part, and that it acts by partially paralysing the motor-cells of the bulbo-spinal centres.

[1] "Asthenic Bulbar Paralysis," THE LANCET, Oct. 21st, 1899, p. 1110.

PRACTICAL HYGIENE FOR FEMALE TEACHERS.

UNDER the Board of Education Act, 1899, a series of lectures will be given at Bedford College, York-place, Baker-street, W., and at the Sanitary Institute, 72, Margaret-street, W., beginning on Saturday, Jan. 19th. The course will consist of 30 lectures, given on Saturday mornings throughout 1901. It will include practical demonstrations, and visits to schools and places where the application of hygiene in practice may be seen. The various subjects—sanitation of schools, physiology for teachers, psychological attitude of the mind towards the study of childhood, will be dealt with by well-known authorities and will be illustrated by experiments, diagrams, drawings, models, and lantern slides. Opportunities will be given to students to obtain practical acquaintance with the various subjects dealt with in the laboratories of Bedford College and for practical demonstration of sanitary appliances in the Parkes Museum. The course is open to women students over 19 years of age who hold either a teacher's diploma or certificate or have had at least two years' experience in teaching in a secondary school, or who can produce satisfactory evidence that they will be able to benefit by the instruction afforded them. Among the names of the lecturers are Dr. J. S. Edkins, Dr. H. R. Kenwood, and Mr. W. C. C. Pakes.

THE HYGIENIC TREATMENT OF PULMONARY TUBERCULOSIS.

IN the letter from our Paris correspondent which appears in another column the report is given of a committee which was appointed to formulate the conditions of admission to the sanatorium of Angicourt, an institution for the hygienic or "open-air" treatment of pulmonary tuberculosis. The committee suggest that the sanatorium shall be open to indigent inhabitants of Paris afflicted with pulmonary tuberculosis but whose lesions "are presumably curable." To assist in the selection of suitable cases it is further proposed that no patient shall be admitted to the sanatorium without his furnishing a certificate drawn up by his medical attendant showing clearly his family and personal history, the history of his illness, and a complete daily clinical record extending over at least eight consecutive days, setting out details of his pulmonary lesions, his rectal temperatures, his pulse, an analysis of his urine, his weight, and the result of a microscopical examination of his sputa. Thirdly, it is recommended that these certificates shall be examined periodically by a medical committee appointed for that end by the Hospitals Medical Society. These proposals are certainly to be commended and might well be adopted by similar institutions in this country—if the various provisions could be carried out. We quite agree with our correspondent, however, as to the numerous difficulties which would arise in this

respect. Physicians who have had experience in out-patient work know how difficult it often is to make out satisfactorily certificates for admission to convalescent homes; still harder would it be to give a precise account of a patient suffering from pulmonary tuberculosis—in fact, in many cases it would be practically impossible to answer the questions suggested by the Paris committee. One way of overcoming the difficulty would be to accept a less complete account of a case drawn up by a medical man, and if from this the case is presumably a suitable one for this form of treatment the patient might be admitted into the institution for a period of probation with the distinct understanding that if the expectation of the case doing well should not be realised he or she would be discharged. We think that such a plan would be more satisfactory than the one suggested by our correspondent, but the whole question is one to which an answer is not easily found.

THE AUXILIARY NURSES' SOCIETY.

THE numerous nursing societies in existence in London are apparently still insufficient to meet all the demands which are made upon them by the profession and by the public. As a rule, there is no difficulty in obtaining a well-trained nurse when the nature of the case requires more skilled aid than can be afforded by the patients' friends, but considerable difficulty is frequently experienced by medical men in obtaining permanent nurses for prolonged and chronic cases, and to supply this want is one of the main objects of a new society which has just started work under the title of "The Auxiliary Nurses' Society." The nurses are all members of the Royal British Nurses' Association, and in addition to their hospital work they have had some years' experience in private nursing. The society aims also at meeting the need for a body of nurses who are qualified by their age and experience to undertake cases in which either on account of the nature of the malady or of the circumstances of the patient it is undesirable to employ the services of younger women. The office of the society is at 10, Orchard-street, Portman-square. We appreciate the objects with which the association has been founded, and think that medical practitioners may be glad to take advantage of the class of nurse enrolled under its membership.

THE Central London Railway Company have met amicably a committee representing the owners of houses in the vicinity thereof, and as a result the Board of Trade, upon the joint invitation of persons representing both interests, have appointed a committee consisting of Lord Rayleigh, F.R.S., chairman, Sir John Wolfe-Barry, K.C.B., F.R.S., and Professor Ewing, F.R.S., to consider to what extent the working of the traffic on the Central London Railway produces vibration in the adjacent buildings. The committee will also consider what alterations in the conditions of working or in structure can be devised to remedy vibration, and will report on the matter to the Board of Trade.

DR. JOHN C. THRESH, county medical officer of health of Essex, reports that diphtheria is excessively prevalent in the county, especially in the rural districts. The epidemic decreases in one district and increases in others and apparently is traversing the whole county.

THE annual general meeting and election of officers of the Harveian Society will take place at the Stafford Rooms, W., on Thursday, Jan. 17th, at 8 P.M., and will be followed by a conversazione, at which there will be an exhibition of objects of interest from South Africa.

THE Lord Mayor has received about £22,000 in all in response to the Princess of Wales's appeal on behalf of the Soldiers' and Sailors' Families' Association. The sums sent direct to Colonel Gildea bid fair also to make a handsome total.

A TELEGRAM has been received by the Colonial Office, dated Jan. 4th, 1901, from the Government of Mauritius stating that during the week ending Jan. 3rd there were 32 fresh cases of bubonic plague, 23 of which were fatal.

AT the next meeting of the Royal Microscopical Society, to be held at 20, Hanover-square, W., on Wednesday, Jan. 16th, at 8 o'clock, the President, Mr. William Carruthers, will deliver his annual address.

REFLECTIONS ON THERAPEUTICS.

BY HARRY CAMPBELL, M.D., B.S., F.R.C.P. LOND.,
PHYSICIAN TO THE NORTH-WEST LONDON HOSPITAL AND TO THE WEST END HOSPITAL FOR DISEASES OF THE NERVOUS SYSTEM.

II.[1]

INSTINCT AND REASON IN RELATION TO TREATMENT.

I HAVE hitherto considered the vis medicatrix as carrying on a purely organic process quite independently of the consciousness of the individual, but we cannot altogether exclude consciousness from among the inherent forces which make for the health of the organism. The conscious individual himself to some extent controls his own destiny; what he shall or shall not eat and drink, what clothes he shall wear, what pursuits he shall follow or avoid—these and many other things of a like nature are yet within the choice of all but the very poorest or most unfortunate, however cribbed, cabined, and confined he may feel his lot; and the question arises how far this mental factor of a volition acting on the initiative of experience operates in the direction of preventing or inducing disease, or of ameliorating or aggravating it when already set up.

The lower animals are guided in matters pertaining to their health chiefly by instinct, which is to them an all but infallible guide. But instinct is only capable of acting as guide to an organism in a comparatively simple environment, and one moreover which has been much the same for many generations past. Given such an environment, and an unerring instinct will in process of time evolve by natural selection. The animal will come instinctively to search after the food that is wholesome, to avoid that which is injurious, and to protect itself against harmful agencies of all kinds; and this instinct will be constantly supplemented by the individual experience, or rather by "reason," if we take that term, as we are entitled to take it, to embrace all mental guidance which is not instinctive, even though it may not rise to the level of a conscious intellectual process. As a matter of fact, animals are helped much more by experience than by reason, as reason is generally understood. If, therefore, there are introduced into the environment factors totally unlike any belonging to the ancestral environment, instinct, hitherto all-sufficing, becomes in respect of these new factors a wholly inadequate guide, and it takes long before, by a weeding out of the unfit, instinctive adaptation again occurs. The moth has not yet evolved the instinct to avoid the dazzling lure of the flame, but if countless successive generations continue to be exposed to the danger of it such an instinct will doubtless in the end evolve, by the survival of those for which the fatal attraction has the least force. Hence it happens that when we domesticate a wild animal we find instinct fail it in many particulars. If offered food of which its ancestors had no experience it has to learn by its own experience to distinguish the wholesome from the noxious. On the other hand, it is remarkable how persistent a primitive instinct may be in animals which have long been domesticated, and in which it has not been called out for many generations. Witness the terror excited in the horse by the smell of the wild carnivora

[1] No. 1 was published in THE LANCET of Jan. 5th, 1901, p. 51.

—a horse passing a menagerie will quiver with panic. The very existence of its wild ancestors depended upon their ability to hold their own against the carnivora. No match for these latter animals in strength their safety lay in their swiftness and their wariness to elude pursuit, and in the latter they were greatly aided by the sense of smell which when acute enabled them to scent their foes from afar; hence this sense became, and it still remains, highly specialised in them.

I say we cannot expect instinct to be a trustworthy guide unless the environment is a simple one and has been stable for several successive generations. It is clear that neither of these conditions obtains in the case of man, especially civilised man. His environment is infinitely more complex than was that of his primitive ancestors, and it has moreover varied, and continues to vary, very considerably from generation to generation—it has become, i.e., unstable and *pari passu* with, and as an inevitable result of, this increase in the complexity and instability of the environment, instinct has become less and less adequate as a guide, and reason more and more essential. Hence with the evolution of reason there has been a concomitant dissolution of instinct, until when we arrive at civilised man we find the one guide all but superseded by the other.

Now this places man at a disadvantage as compared with the brutes, since the guidance of reason is not by any means so trustworthy as that of the instinct which it has replaced. It is needless here to enter into a psychological exposition of the defects of reason as a guide for man.[2] To do this with any sort of fulness and completeness would be to write a book on human error. But what does concern us, and that most intimately, is that under the working of this new arrangement, as we may call it, man is continually going wrong in matters physiological, and it is most difficult to set him right. Do not we physicians see him persistently sinning against the laws of health, and that with a temerity that would be utterly amazing did we not know that beneath the temerity there lies a still more astonishing ignorance of all the laws of his being. It is often a task of much difficulty to enforce the most elementary principles of hygiene even among the educated classes; among the uneducated it is well nigh impossible. Soldiers on campaign prefer the risk of contracting typhoid fever to the trouble of boiling their drinking-water, and in India the enforcement of sanitary precautions against such terrible pests as cholera and the plague is not only stubbornly resisted, but leads not infrequently, especially if it runs counter to racial and religious prejudices, to riot and bloodshed. We have had instances of this in Calcutta, in Poona, and in Cawnpore only just recently, and it was but a few weeks ago that the newspapers had to record the acknowledged failure of the Indian Government to enforce the plague regulations, and its consequent resolve to give up the attempt to stamp it out by coercion. "It is hopeless," so runs the report of the official committee appointed to collect evidence, "to carry out effectively any system of plague administration which runs counter to the feelings, susceptibilities, and prejudices of the people." But what a comment is such a statement as this on reason as a guide instead of instinct. Nothing, however, so strikingly shows its inadequacy as the flagrant errors into which it allows mothers to run in regard to the up-bringing of their offspring, and in one particular—the *feeding* of children—I shall seek in its proper place to show that even the specialist physician with all his knowledge has still much to learn.

Instinct fails civilised man in respect both of food and exercise, and, as regards the former both in respect to its quality and its quantity. Sir William Roberts has said that a man's palate constitutes his dietetic conscience, and doubtless the palate is a useful guide, as it is also certainly the one most acceptable to the "natural man." But it is with equal certainty by no means to be depended on as a wholly safe director. The food of civilised man is presented to him in such an appetising and so highly concentrated a form that he is led to eat not only much that is bad for him but also too large a quantity. The individual with a constitutionally clamant appetite is thus far defective as regards his instinct; he derives great pleasure from eating and this leads him almost certainly, his inward monitor failing him, to injure his health by eating too much, and the better his teeth and digestive organs the more likely is he to do this. A wise physician used to say to his gouty patients with strong, hard teeth: "You have good teeth: take care you do not dig your grave with them." Those with constitutionally small appetites, on the other hand, are better equipped in respect of food-instinct, and escape a great deal of trouble in consequence. Here I may refer in passing to the cravings of some people, especially pregnant women, for particular foods. These, though often morbid and hurtful if indulged in, may yet be physiological promptings.

Instinct also often fails to prompt man to take the normal amount of exercise. In the natural state animals are compelled by the struggle for existence to lead active lives, and apart from this they take exercise—especially the young ones—for the sheer pleasure of it; but, as we have seen, in the case of civilised man the struggle for existence does not necessarily entail much exercise, and if not prompted by instinct to take his proper share he suffers in consequence. If, then, man's mental guide fails him even in regard to the most elementary laws of health, how much more untrustworthy must it be as a guide to health-conduct in its more complex bearings.

THE MENTAL GUIDE IN DISEASE.

It being so clearly manifest that as concerns the avoidance of what is calculated to cause disease man's guide is imperfect, we have next to ask how far it may be trusted when he is already suffering from disease. How far do instinct and reason help the sufferer to get well? In answering the question we must bear in mind that in so far as they help at all they must be regarded as part of the vis medicatrix. It is in wild animals again that we find instinct operating most effectively in disease as well as in health. These lick their wounds and keep them exposed to the fresh air, thus anticipating the most recent advances of surgery in their efforts, nature-led, to render them aseptic; there is good reason also to believe that they seek out herbs for their medicinal virtues. We know that our domesticated dog eats grass, apparently for the purpose of inducing vomiting. A sick animal will creep into some dark corner, not only to hide from its foes, but for the rest and quiet so needful in grave disease; and doubtless instinct manifests itself among the lower animals when attacked by disease in many other ways unnoticed by us, ever acting, we may be sure, with that unerring wisdom which characterises all the measures of the great vis medicatrix.

One would expect that if instinct ever asserted itself in man, and asserted itself effectively, it would be in disease especially that it would do so; for disease dates back through untold generations—is, in fact, as old as life itself. And if the vis medicatrix, working on purely organic lines and independently of consciousness, can, as she does, combat disease by means so complex and so potent, we should certainly expect consciousness also, when it comes into play in even the lowly form of instinct, to be a not unimportant factor in the ultimate results. And let it be remembered in this connexion that disease in its fundamental nature is the same in man as it was in his anthropoid ancestors, or in those yet more remote and primitive species that reach back in unending line beyond these into the dim dawn of being. I therefore do not see the same reason for supposing that instinct so far as it determines man's conduct in disease should have atrophied in the same way as it has as a determiner of conduct generally. There is yet another argument that may be urged in support of this view. Disease is a process of dissolution; in it man unevolves—if I may use the clumsy expression,—slipping back to the condition of his more primitive ancestors in whom we find instinct in its most perfected and effective form. We should therefore expect him to display—and there can indeed be no doubt that he does display—curative instincts in disease. The malaise, for instance, which attends acute illnesses, and especially in their onset, secures the rest which is so sorely needed, and we can best realise the great healing value of such premonition by calling to mind those cases of typhoid fever in which, owing to its absence, the patient has not taken to his bed until the disease has got a fatal hold. Again, the loss of appetite and the thirst in fever assuredly serve a good end, and the same may be said of the malaise of megrim, compelling as it does rest of mind and body. The loathing of food felt during the attack further secures rest of the digestive organs and the good effect is enhanced[3] by the nausea and vomiting (which are almost of

[2] See on this subject, Campbell: "The Causation of Disease," p. 197.

the nature of instincts) by which the flow of bile is stimulated and toxic substances are removed from the body. These instinctive promptings are therapeutically suggestive. Many people, I believe, would be greatly benefited by an occasional 24 hours' fast and copious emesis, though the treatment is of such a nature that few will submit to it. The exquisite pain felt in the arthritis of rheumatic fever is also of the nature of a curative instinct, fixing the joint as in a splint, and by the rest which it thereby secures to it placing it in the best position for recovery. If only the inflamed cardiac valves could be similarly rested who knows but that the endocarditis might clear up as completely as the arthritis? At all events, the valves would not be permanently damaged to the extent they actually are.

It would, of course, be unsafe to allow our patients always to follow their instinctive promptings—in the matter of diet in typhoid fever, let us say—but we shall do well, I think, to heed them more than we do. I could relate more than one instance of patients obeying their instincts in express contradiction to the orders of their medical attendants, and with the happiest results. I remember the case of a woman with acute mammary abscess being ordered not to put the child to the affected side; the result was that the breast got larger and larger, and in three days it had attained enormous dimensions, the pain becoming acute. Unable to bear it, she disobeyed the medical man (who had, indeed, forgotten to order the milk to be drawn off) and she obtained immediate relief. I can also recall the case of a man who was in bed for many weeks with urethral fever and steadily getting worse. He was always saying he should never be well so long as he stayed in bed, and one day he took the law into his own hands, got up, and walked about the street, and from that time forward he never, as he said, "looked back." I do not cite these cases as affording precedents, but in order to warn the physician against turning an altogether deaf ear to a patient's instinctive promptings and to impress upon him the desirability of being prepared to consider how far they may be indicative, and as a consequence, safely indulged. As a set-off against the cases just quoted in which instinct proved a safer guide than the physician, I may mention the case of a child, a very poor hospital patient, who, when asked a few hours before his death if he fancied anything, promptly replied that he would like some "cheese and treacle"—presumably the supremest luxuries which his poverty-stricken home had afforded. Here the prompting was scarcely physiological, but he was beyond the stage at which the indulgence could harm him, and in obedience to the principle of euthanasia he was allowed to gratify his desire.

THE EXPERIENCE OF THE INDIVIDUAL AS A HEALTH GUIDE.

While instinct is, as we said just now, a most faulty guide to man under his present conditions, very valuable guidance may be derived from his individual experience as to what is good or bad for him. Individuals differ so much in their idiosyncrasies that it is only in respect of broad general principles that the physician can give stereotyped advice which shall be applicable to all. Hence he is often compelled to fall back upon the patient's experience, since in respect of many things each individual is a law to himself. Some are made rheumatic or gouty by meat, others can eat large quantities with impunity; some need to take much exercise to keep well, others can keep quite well while leading a sedentary life; and so on. It is especially in regard to food and drink that personal experience is helpful, and it behoves every man to find out for himself what things do and what things do not suit him. This truth is embodied in the saying that "a man is either a fool or his own physician at 40." Applying this test I fear we must conclude with the sage of Chelsea that an immense number of men are fools. In the first place, people often take an astonishingly long time to find out that a certain thing is injurious to them, and secondly, even when they do make the discovery they often do not choose to act upon it. Incredible as it may seem, I have known a man fail to realise till considerably past 40 years of age the fact that he always felt ill the day after he had dined out and eaten and drunk with less than his usual abstemiousness. It was only by casting his mind back and carefully thinking over the matter that the truth was borne in upon him that for every digression from his usual habit he had to pay the penalty of a day's purgatory. Such extreme cases are probably rare, but it is certainly very common for persons to fail to realise adequately a quite obvious causal connexion between ill-health and acts of "physiological unrighteousness." I recently spent a day with one of the most brilliant and sanest writers of our time, one therefore who cannot be accused of want of intelligence, and during the whole of the time he was smoking, save only at table. As fast as he finished one cigar he lit another from it, and he told me that he had smoked in this way since he was 16 years of age (he is now past 60) except for one or two short periods of abstinence. It was quite clear to me that he was suffering from chronic nicotine poisoning, and I have little doubt that his recent work has suffered on this account. Yet he has never realised that the habit has harmed him; indeed, he argues that it must have done him good, because on one occasion when he left it off for a time the work which he then did was much below his standard; and no doubt the sudden abstinence, after long habituation, did interfere with his mentation, though I utterly dissent from the conclusion which he deduced.

But while it is wise and right that the individual should seek to find out by experience what is good and what bad for him, it is by no means desirable that he should go to extremes and allow the pursuit of health to become the religion of his life. This is despicable, and it moreover brings with it its own Nemesis, for it leads to a morbid alertness for unfavourable symptoms and a constant dread of disease and death.

HISTORY OF THE HOUSING QUESTION IN LONDON.

PART I.

UNDER THE METROPOLITAN BOARD OF WORKS.

THE London County Council have just issued a book that will be of great value and use to all who are interested in the question of the housing of the poor. Considering the extensive nature of the subject, it gives in a comparatively compact form a summary history of what has been attempted and of what has been done. The committee of the County Council on the Housing of the Working Classes instructed Mr. C. J. Stewart, the clerk of the Council, to arrange for the production of such a record. Under his supervision the work has now been prepared by Mr. W. J. Russell and Mr. M. H. Cox, LL.B. Lond., and consists of a volume of some 400 pages, to which many maps of insanitary areas, model dwellings, &c., are added.[1] In regard to administrative action this history cannot, of necessity, date further back than 1855, when the Metropolitan Board of Works came into existence; but in regard to legislative action the record commences with the Shaftesbury Act of 1851 which was the first enactment dealing with the housing question. We are reminded how in April, 1851, the great Lord Shaftesbury, then Lord Ashley, called the attention of the House of Commons to the disgraceful condition of the houses inhabited by the poorer classes, and related that in one of the wealthiest parishes of London—St. George's, Hanover-square—there were 929 families which had but one room for each family, and 408 families had only two rooms. What, then, must have been the condition of less favoured localities? Lord Shaftesbury's able advocacy led to the passing of the so-called Adoptive Act, which is the first law on our statute book dealing with the question (14 & 15 Vict., c. 34). By this Act the local authority could borrow money on mortgage and itself lease or build houses for the working classes. As may be surmised by its nickname, this, the first Labouring Classes Lodging Houses Act, was not obligatory and could only be enforced when the local authorities by a special vote and with a two-thirds majority had declared their wish to apply its provisions. Considering what the vestries were in those days it is not surprising that at first nothing was done. On the other hand, the Common Lodging Houses Act of 1851, together with its amendments bearing the date of 1853, proved one of the most effective and beneficent laws ever enacted on this question. The carrying out of this law was not intrusted to

[1] The Housing Question in London. Printed for the London County Council; published by Messrs. P. S. King and Son, Great Smith-street, Westminster, S.W.

supine and corrupt vestries, but to the Metropolitan Commissioner of Police; consequently, of all the dwellings likely to become unhealthy and overcrowded, none have been so constantly inspected and so well controlled as those that come under the denomination of registered common lodging houses. This experience alone would suffice to show that some authority with wider powers, greater ability, and responsibility than was generally to be found in the vestries is needed if any real reform is to be effectively carried out.

No other great town in England or in Europe presented such a sorry spectacle as did London. Possessing no central local government of its own, no municipality, the metropolis was divided up into innumerable petty district bodies whose functions overlapped and clashed with each other and who were better able to hinder than to forward any great progressive measure. It was to mitigate the evils of this chaos that the Metropolitan Board of Works was brought into existence in 1855 by the Metropolis Management Act (18 & 19 Vict., c. 120). The Metropolitan Board of Works was elected in the second degree; that is, not by the ratepayers but by the ratepayers' representatives or vestrymen. It replaced the old Commission of Sewers, and it did not possess at first any powers to deal with the housing problem. The incompetence of the smaller local bodies had to be further demonstrated before the central body was authorised to intervene. Thus the Nuisances Removal Act of 1855 and the Sanitary Act of 1866 sanctioned the imposition of regulations fixing the number of persons allowed to occupy such houses as had been brought under these Acts and to provide for their registration, inspection, cleansing, and lime-washing, but it depended upon the energy of the vestries or district boards as to whether this law should be applied to any of their insanitary areas. Needless to say that as the law was not obligatory it was not very largely applied. The Labouring Classes' Dwelling Houses Act of 1866 and 1867 extended the time for the repayment of money borrowed for building purposes to 40 years. This was followed by Torrens's Act of 1868, establishing that "the responsibility of maintaining his houses in proper condition falls upon the owner, and that if he fails in his duty the law is justified in stepping in and in compelling him to perform it." Further, the local authorities were now called upon to appoint medical officers of health in their respective districts who should visit and report upon any unhealthy houses, and the local authority was empowered to force the owners of such houses to put them in order. When this was not done the local authority might even proceed to pull down a notoriously unhealthy house. In time this power was extended and by the Labourers' Dwellings Improvement Act of 1875 it was made to apply to "whole areas, where the houses are so structurally defective as to be incapable of repair, and so ill-placed with reference to each other as to require, to bring them up to a proper sanitary standard, nothing short of demolition and reconstruction."

As important perhaps as the Act itself, commonly known as Cross's Act, 1875, is the fact that its application was no longer intrusted to the vestries but to the Metropolitan Board of Works which had just been created. By this new law the medical officer of health, two local justices of the peace, or 12 ratepayers had the right to make representations to the Metropolitan Board of Works concerning any insanitary area in their district. The Metropolitan Board of Works had then to investigate the matter and if the facts stated were confirmed to draw up a scheme dealing with such area. Provision was to be made for supplying in the same district dwellings for at least as many persons as would be deprived of their homes by pulling down the condemned houses. Owners who were not satisfied with the scheme had the right to appeal to the Secretary of State for the Home Department and the latter was obliged to investigate their claims. This left the door open for much disputation and delay, and then when an area had been cleared the Board was not itself to rebuild but could only impose certain conditions on those who at their own risk and peril undertook to rebuild. Of course, the more these conditions were made suitable to the needs of the case speculators and investors became less and less inclined to undertake the work. Then for the compulsory purchase of the property, if an amicable arrangement could not be concluded, an arbitrator had to be appointed by the Secretary of State, and where the amount of compensation claimed exceeded £500 there was a right of appeal from the arbitrator to a jury.

Within the first four years of the passing of Cross's Act the Metropolitan Board of Works took action in regard to 11 schemes, and soon found that this law facilitated the obtaining of excessive compensation and all manner of delays and unnecessary expenditure. Under such circumstances schemes for re-housing the poor could not be made to pay. The Board entered a formal protest against giving as heavy a compensation for dilapidated, neglected, and insanitary property as if it had been property kept in perfect repair and order. It suggested that the cost that would have to be incurred if the houses were rendered habitable should be deducted from the amount of compensation to be paid. If, however, the houses were so bad that they could not possibly be rendered habitable, then the compensation should be only equal to the value of the land and the materials on the ground. The Board also sought to be relieved from the obligation of re-housing the same class of people in the same locality. Nobody would buy the sites under these conditions at a sufficiently high price and the Board had been obliged to sell the area cleared under the Whitechapel and Limehouse scheme of 1876 to the trustees of the Peabody Fund at a price calculated on a 20 years' purchase of a rent of only 3*d*. per square foot. Powers, also, the Board claimed, should be given to stop alterations while negotiations were proceeding, as such alterations were often undertaken only with the view of obtaining higher compensation. These representations made by the Metropolitan Board of Works led to the passing of the second Cross's Act in 1879, which, however, only improved the situation in matters of detail, for the main difficulties remained. Further representations were therefore made in 1880. It was also found that Torrens's Act had not effected the improvements anticipated. The repairs made by the owners were often considered sufficient by the justices to whom the owners appealed, though in reality such was not the case. In fact, the question arises whether in these technical matters the ordinary justices are competent judges. But the matter was complicated by a contest that soon arose between the vestries and the Metropolitan Board of Works, both parties seeking to throw upon the other the cost of the necessary reforms. The vestries wanted the Board to act under Cross's Act, and the Board wanted the vestries to proceed under Torrens's Act. It is true that the second Torrens's Act, which bears the date of 1879, gave the Board the power to do what the vestries had neglected to accomplish and place the cost on the rates paid to the vestry, but the Board shrank from the complicated litigation that such action would occasion. Thus this important clause of the Act has never been enforced. There was also another defect in Torrens's Act. A house, if pulled down, had to be rebuilt on precisely the same site, so that the want of open space in front or behind remained the same as before and in many parts of London the grievance was not only the condition of the houses but the fact of their being too closely crowded together.

The Metropolitan Board of Works never had the ambition or desire to build any artisans' dwellings. Whenever it was suggested that some particularly unwholesome site should be cleared their first care was to ascertain if any artisans' dwellings company would be willing to purchase the land and to build upon it. At first, it is true, they inserted clauses in the agreement that the land should be used in perpetuity for artisans' dwellings, but subsequently this was limited to a number of years and finally to only 10 years. So that there are now in London a certain number of artisans' dwellings, built more than 10 years ago, which can be converted into offices or warehouses or used for any other purpose.

Under all these circumstances the progress was so slow that Parliament appointed a Select Committee in 1881 to investigate why the various Acts dealing with the housing question had been so difficult to apply, and as a consequence of this inquiry we had the Artisans' Dwelling Act of 1882. This new enactment gave to the Secretary of State for the Home Department the right to dispense with the necessity of providing dwellings for more than half of the persons displaced by an improvement scheme; it raised to £1000 the amount of compensation entitling appeal to a jury; it provided that a grievance affecting not more than 10 houses could be dealt with under Torrens's Act, and that buildings which stopped ventilation could also be purchased. Finally, it was stipulated that improvements effected after representations had been made of insanitary conditions should not be allowed to raise the amount of compensation claimed. Now that the re-housing stipulations had been relaxed by the Act of 1882

the Metropolitan Board of Works took immediate action. Its plan was to clear a portion of a condemned area and not to deal with the remainder till the first portion had been rebuilt. This, however, did not solve the difficulty of maintaining the remaining portions of such areas in a habitable condition. Then the Board, in purchasing, had to pay the market value of the land, and in selling it obtained—for instance, in the Whitecross-street scheme in St. Luke's—3*d*. per square foot for what it had bought at 1*s*. 2*d*. per square foot. Altogether, from 1875 to 1889 the Metropolitan Board of Works spent on its re-housing schemes £1,983,892 and only recovered £377,114. Thus the loss or net cost amounted to £1 606.778. This looks very like a subsidy of more than £1,500,000 paid by the ratepayers to the 5 per cent. philanthropists who benevolently consented to buy land which was worth 1*s*. 2*d*. per square foot at 3*d*. per square foot, so as to provide better dwellings, not for the extreme poor but for that more prosperous and steady class of artisans which was not, in those days at least, in such urgent need of help. Then, after all, the accommodation afforded was insufficient; for 29,151 persons were displaced—that is, forced to leave their insanitary houses, and the model dwellings built instead only accommodated 27,780 persons. Apart from these figures the Board, it is stated, left to its successor, the London County Council, a legacy of some 4000 persons for whom homes should be provided, but this was reduced to 2457 by the Secretary of State.

It is not surprising if, in the face of this disastrous aspect of the problem, it was found necessary to make further investigations and efforts. Hence the Royal Commission which, at the proposal of the Marquis of Salisbury, was appointed in 1884 with H.R.H. the Prince of Wales as chairman. Of course, this commission had to report that the law should be more strictly applied—that in spite of the improvements effected the overcrowding was becoming more serious every year. There were Torrens's Acts, which compelled the owner to keep his property in proper order, and there were Cross's Acts, which when this could not be done sanctioned wholesale expropriation, purchase, and reconstruction on insanitary areas. Then the report described at length the prevailing insanitary conditions, the insufficient water-supply, and the terrible overcrowding, and asserted that the overcrowding was mainly caused by abnormally high rents, arising from the competition among tenants to secure tenements. This was due to the necessity of living near the places where work was to be obtained and to the demolition of houses formerly inhabited by the poor, so as to carry out public improvements, build railway lines and stations, &c. The commissioners recommended that the vestries should increase their staffs by appointing a greater number of better qualified sanitary inspectors, so that lodging-houses might be more strictly controlled and cellar dwellings be abolished. The failure, the commissioners thought, was in administration rather than in legislation, but still they suggested various amendments to the existing laws. Greater facilities for borrowing money, they urged, should be given, and prisons should be removed to outlying districts and their sites used for artisans' dwellings. The compulsory purchase of land should be rendered more easy and less expensive. The railway companies were to be urged to organise workmen's trains and were to be compelled to provide for the re-housing of such of the poorer class of tenants as were disturbed by the building of railway lines and stations.

This report of the Royal Commission led up to the adoption of the Housing of the Working Classes Act of 1885. This Act gave power for the sale to the Board of the site of several prisons. In other respects it introduced no new principle and aimed only at facilitating the application of existing laws; for instance, it rendered the appeal of the owner of condemned property from the arbitrator to a jury somewhat more difficult, it extended the meaning of the words "lodging-houses" to separate houses or cottages for the labouring classes whether containing one or several tenements, and it somewhat facilitated the process of expropriation and purchase. This was the last Act passed to facilitate the endeavours of the Metropolitan Board of Works. The next law was the Local Government Act of 1888, which brought the County Council of London into existence. To sum up the history of the question of the housing of the working classes up to the time when the Metropolitan Board of Works ceased to exist it might be described by the sceptic as an effort to make an omelette without breaking eggs. As a matter of fact, of course, for what omelettes were made eggs had to be broken. The question arises whether the right person was made to pay for the eggs. Under the Metropolitan Board of Works the cost mainly fell on the ratepayers, and it may well be objected that the burden might be more justly imposed on those who were responsible for the degradation of the property condemned.

THE PREVALENCE OF MOSQUITOES AND MALARIA IN THE COLONY OF HONG-KONG.

THE following preliminary report by Dr. J. C. Thomson of the Medical Department of the Hong-Kong Civil Service has been issued in the form of a letter to Dr. J. Bell, acting principal civil medical officer in Hong-Kong, regarding a research into the relation of mosquitoes and malaria in Hong-Kong and the New Territory. After a few preliminary remarks Dr. Thomson says:—

There are two distinct species of anopheles abundant in the colony, differing in size, general appearance, and the markings on the wings. The smaller, which I believe to be anopheles costalis, is prevalent all over the colony and in the ravines to the south of Magazine Gap; the larger, anopheles sinensis, is the more common throughout the New Territory, on the islands, and at Stanley and Pokfulam. While the area of general prevalence is thus different it is not exclusively so, as I have myself caught anopheles sinensis in the centre of the city in a hotel not far from the clock tower, while anopheles costalis has been included in some of the consignments from the mainland.

I have differentiated at least eight distinct species of culex, but I prefer not to commit myself to the naming of them until my classification has been confirmed or amended by an expert entomologist. To secure this I have sent to the London School of Tropical Medicine 54 mounted specimens, consisting of 14 different species of mosquitoes, two species being anopheles, eight species at least being culex, and the remaining four species probably belonging to other genera of the mosquito family, though one or two of them may prove to be species of culex. All the above have unspotted wings, excepting the anopheles and a single species of culex, of which I have obtained only a single specimen. This I believe to be culex mimeticus, and it is manifestly very rare. A good general rule, therefore, in Hong-Kong, in addition to the differences of the head appendages and the characteristic attitude when at rest that distinguish anopheles from culex, is that a mosquito with spotted wings is probably one of the dangerous anopheles, and one whose wings are unspotted is a culex. I have privately submitted a few of the more prevalent types of both genera for His Excellency the Governor's inspection.

[Dr. Thomson then goes on to refer to the breeding-grounds of anopheles. This insect chiefly affects the natural water-courses, and the favourite locations of the larvæ are the little breaks in the rocky surface by the side of the stream where there is just enough current to prevent stagnation. As far as the city of Victoria is concerned the question of dealing with anopheles pools reduces itself to the "training" of the nullahs—namely, clearing away undergrowth and levelling the bed so that there is a smooth waterway down which the water can rush rapidly. Dr. Thomson continues:]

Concurrently with my inquiry into the prevalence of anopheles I have been investigating the prevalence of the malaria parasite in the colony. Its connexion with anopheles is now an accepted fact. The general mosquito-malaria theory has been proved to the hilt and has recently been brilliantly demonstrated to the public by Manson's double experiment, but the connexion of malaria with disturbance of soil, an important point in Hong-Kong, is by no means clear as yet. Grassi disposes of the subject by stating that it depends on the creation during digging operations of puddles of water in which anopheles breeds. This certainly does not hold for Hong-Kong. The whole of the broken earth surface may show no single puddle the sun drying the superficial layers as they are turned up, and yet it is a fact of experience that in certain parts of the colony earth cutting is invariably attended by an outbreak of fever. On the other hand, there is undoubtedly some

connexion with the presence of moisture in the soil. In certain localities—e.g., around MacDonell-road, where earth-cutting may go on to an unlimited extent with impunity—I find that the soil is comparatively dry, while in others—e.g., the West Point already referred to, where the slightest excavation inevitably produces fever in the neighbourhood—I find that the soil is more or less water-logged. I propose to give attention to this question, which is one very seriously affecting this colony.

There are three main types of malarial fever, associated with different and corresponding parasitic organisms, and all the three types of the parasite I have found prevalent in Hong-Kong—the benign tertian parasite, easily yielding to the action of quinine; the quartan parasite, readily brought under control by the same drug but difficult to eradicate; and the malignant parasite, variously described as æstivo-autumnal by Italian observers, tropical by Koch, pernicious, &c., less amenable to quinine, more severe in the resulting symptoms, and more apt to produce a fatal result or prolonged ill-health.

Of 50 cases in which, up to Oct. 31st, parasites were found and their form and type recorded three came from Kennedy Town, 18 from the west part of the city, 13 from the central parts of the city, six from the east part of the city, two from Happy Valley, and eight from outlying villages.

The most common type of the parasite in the cases which I have examined has been the malignant parasite, with abundant crescentic forms; but I do not consider that this gives the true proportion of the prevalence of the different parasites in the colony, since probably only the more serious cases of fever find their way into the hospital wards.

There has recently been a small epidemic of fever in the neighbourhood of the naval hospital and Morrison Hill-road. My first opportunity of personal observation in reference to it occurred on Oct. 27th, when I was requested to see the family of an European Government officer whose four children had all suddenly become ill with high fever. I took a microscope to the house and found the benign tertian parasite in the fresh blood of three out of the four cases. All readily yielded to quinine, and by Nov. 1st they were back at school. I requested the father of the patients to catch for me some of the mosquitoes frequenting the house, and the first he submitted was a specimen of anopheles costalis.

While pursuing this investigation into the prevalence of mosquitoes in the colony and its dependencies, chiefly with reference to the question of the presence of anopheles and the means to be adopted for its extermination, my attention has been directed most forcibly to the enormous prevalence of mosquitoes of the genus culex. As has been mentioned, I have differentiated at least eight species of this genus. The culex mosquito does not, so far as is yet ascertained, act as a host to the malaria parasite; but it, as well as anopheles, is certainly the intermediate host of the minute parasitic blood-worm, the filaria nocturna or filaria sanguinis hominis, whose adult form lies in the lymph vessels and is the cause of the great group of elephantoid diseases. Elephantiasis is quite common among the Chinese in this region, though, for some reason not yet sufficiently explained, Europeans are as a rule exempt from it, an exemption, however, by no means complete; but most Europeans are affected by the immediate disagreeable effects of the bite of the mosquito, and few are aware that the daily supply of these vicious little insects is being produced in their own houses.

I think public attention should be drawn to this fact. I would like to write it in large capitals that I have found the larvæ of culex in process of development in abundance in or about every house without an exception in which I have looked for them. A few instances will illustrate the great variety, and also the common general character, of their breeding-places: at the Alice Memorial Hospital I found them in an old teapot on the roof-balcony; at the Tung Wah Hospital, in the ornamental flower-stands; at the gaol, in an empty pot in the coal store; at Kennedy Town Hospital, in the fire-buckets; behind a house at the Peak, in a disused hand-basin; in another house at the Peak, in a dish placed to catch the water-drippings from the ice-chest, &c. In all these cases they were in abundance and were daily giving off large numbers of full-grown mosquitoes for the supply of their respective localities.

The crusade against the mosquito should include the culex as well as the anopheles. Anopheles must be dealt with by the Government chiefly, though owners of property may probably find it to their advantage to move privately in this matter as well; but culex can be exterminated, or at least greatly diminished in numbers, by individual action alone. It may be impracticable to secure individual action of a sufficiently widespread character to make much impression on the sum total of the culex mosquitoes in South China, but every householder in Hong-Kong has it in his power, by due attention to his verandahs, back-yard, and coolie quarters, to secure that in his own house at least there shall be fewer mosquitoes in the future than there have been in the past. Many are aware that what they have often seen in such receptacles as I have described are the larvæ of mosquitoes; but few realise that these same wriggling creatures will a few days later rise from the surface of the water as adult insects and will probably find their first meal of blood within the house that harboured them in the larval stage.

Since the foregoing was written a fact of very great practical importance has been brought to my notice by Mr. W. J. Tutcher. The anopheles occasionally departs from its usual habits and may breed in artificial collections of water. With Mr. Tutcher I examined one of the Chinese flower nurseries at West Point, that to the east of the house called "Nullah Side," from its location, and found in many flower-pots containing water the larvæ of anopheles and culex side by side. This observation does not affect the practical deductions I have already drawn regarding the usual breeding-grounds of the anopheles; but though I think it will be found that what I have above noted only occurs in the immediate vicinity of anopheles-containing ravines, it greatly intensifies what I have said as to the desirability of everyone doing his best to prevent vessels containing water from standing about yards or verandahs without being frequently completely emptied.

With reference to these Chinese gardens at West Point I would recommend that the Sanitary Board should be requested to cause an officer to periodically inspect them, and treat as a nuisance any vessel containing visible larvæ. Before making this recommendation I have received the assurance of Mr. Tutcher that the vessels containing the larvæ were not in a stagnant condition for any reason connected with the flower-producing industry, and could equally well be kept fresh; and in a neighbouring garden which I visited this morning in pursuance of my inquiries I found as many vessels containing water but hardly any containing larvæ. The owner of the garden told me that he frequently empties all dishes on account of what he called the water-mosquitoes. It would therefore be no hardship to insist on these nurserymen keeping their gardens in a condition better calculated to promote the public health.

In conclusion, I ask permission to quote a passage bearing on what I so urgently insist upon from a speech delivered so recently as Oct. 3rd at the London School of Tropical Medicine by Sir William MacGregor, K.C.M.G., C.B., M.D., &c. He says:—

"We have also to face the immense fecundity of the mosquito. Ficalbi says one mother mosquito may in the fifth generation be the progenitor of 20 milliards. Howard shows that one rain barrel may contain 19,110 larvæ, and that they may produce at least 12 generations in one summer. This at 70 eggs a mosquito would produce in a summer a number of mosquitoes expressed by 25 figures."

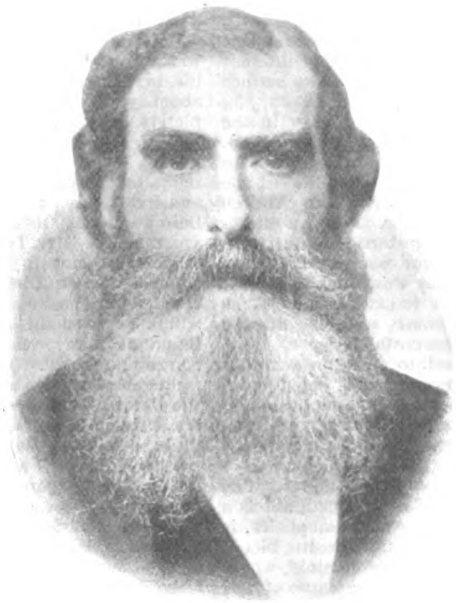
THE ROYAL INFIRMARY, PRESTON. — As a memorial of his son, Mr. Herbert Davies, M.B., Victoria University, who died in South Africa, Alderman Davies of Lancaster has announced his intention of giving £2000 to this infirmary.

PROPOSED PUBLIC HEALTH LABORATORY FOR DEVON AND CORNWALL.—The Sanitary Committee of the Plymouth Town Council has appointed a "Public Health Laboratory Sub-committee" on the advice of the chairman, Mr. W. Paul Swain, F.R.C.S. Eng., and the medical officer of health, Mr. F. M. Williams, "to promote the provision of pathological facilities for the examination of infectious disease in the poorer classes and to obtain the coöperation of the county councils of Devon and Cornwall." As the "sanitary conscience" of the West of England is not yet awake to the need of a county sanitary staff (medical officer of health, bacteriologist, &c.) to apply concerted and expert action to the prevention of disease, the scheme for a laboratory is warmly to be commended. It expresses the opinion of Plymouth, which, with its large population, is the most weighty in the two counties.

Obituary.

JOHN BAPTISTE POTTER, M.D. EDIN., F.R.C.P. LOND., M.R.C.S. ENG.

WE announced last week the death of Dr. J. B. Potter, obstetric physician to the Westminster Hospital, and are certain that a large circle of friends and contemporaries heard the news with deep regret and probably with some surprise. Born in 1839 Dr. Potter was barely 61 years old, an age at which many medical men and most consultants are in full work. But for five years at least his health had been failing, and latterly the declining process had gone on more rapidly. He had the objection, occasionally seen in medical men, to take advice—he would not put himself into the position of a patient. Shortly before his death several professional friends and colleagues, especially Dr. Allchin and Mr. Macnamara, did all that medicine or surgery could do to mitigate suffering and to preserve life, but their care proved unavailing, for Dr. Potter's exact condition only became known to them when nothing could be done. They were well seconded in their efforts by the nurses of the Westminster Hospital, which had been the chief field of his labours for 20 years, and where he died almost literally in harness.



JOHN BAPTISTE POTTER, M.D. EDIN., F.R.C.P. LOND.,
OBSTETRIC PHYSICIAN TO THE WESTMINSTER HOSPITAL.

Dr. Potter was born in London and was the son of Cipriani Potter, musical composer, and for many years principal of the Royal Academy of Music. He was educated at the Kensington Grammar School; his proclivities were mathematical, though he inherited enough musical faculty from his father to play fairly well and to enjoy good music whenever he could get it. He began his medical life with apprenticeship to Dr. Sloman of Farnham. He attributed many useful lessons, especially familiarity with drugs and their uses, to this experience and he was a great advocate of medical pupilage in some form. He entered University College Hospital in 1858 and became Member of the Royal College of Surgeons in 1862. Thereafter he proceeded to Edinburgh, where he graduated in 1863. Between this time and 1870, when his connexion with Westminster Hospital began, he was occupied in various ways. He held certain resident appointments in a Birmingham hospital, travelled with a patient for six months in Ireland, held some subordinate appointment in the Hospital for Children, Great Ormond-street, and in the year 1866 did temporary sanitary work in connexion with the outbreak of cholera in that year. In the year 1870 Dr. Potter was appointed assistant obstetric physician to the Westminster Hospital under the late Dr. Frederick Bird, who died in 1874, when he became full obstetric physician, as he continued to be to the time of his death. He was also lecturer on midwifery and diseases of women in the Westminster Hospital Medical School. He was an obstetrician rather than a gynæcologist and had a good consulting practice. Those who have had the benefit of consultation with him in the emergencies and difficulties of midwifery will remember with pleasure his clear head and his ready help.

Dr. Potter will be greatly missed in the medical societies, and especially in the Obstetrical Society of London, where he filled every office in a way to excite the respect of his colleagues and promote the prosperity of the society. He was on the council from 1872 to 1876 and again from 1890 to 1892, librarian from 1877 to 1878, vice-president from 1879 to 1881, and treasurer from 1882 to 1884 and again from 1893 to 1897. He was on the board of examiners for midwives from 1883 to 1884. He was president of the society in 1885 and 1886, and at the time of his death he was a trustee. In his inaugural address as president he laid stress on the importance of good general training for obstetric physicians and uttered a warning, not altogether unneeded, against excessive specialism. Such a history is sufficient to show the esteem in which he was held by his colleagues. Though he seldom obtruded his views on the society, whose Transactions contain but few communications from him, his administrative services were greatly appreciated. On the committee of the Society for the Widows and Orphans of Medical Men he was one of the most active and useful members and was at the time of his death both trustee and treasurer. Though a London man, nurtured at University College, he graduated at the University of Edinburgh and his services to the Edinburgh University Club, of which at the time of his death he was co-trustee with Sir Dyce Duckworth, will not be forgotten by his co-graduates. He was one of the earliest members and no dinner of the club seemed complete without his presence. Though for his position he was one of the silent members of the profession, it will be seen how many offices he filled and with what confidence and esteem he was regarded by his colleagues. We have before us a few words on his character from one who practised in the same walk of the medical profession as himself and whose praise would be regarded as of the highest value. In this estimate of Dr. Potter occur the following words: "He was an excellent fellow, high-toned and straight as a die and incapable of doing a wrong thing." And this is the opinion which Dr. Potter had earned for himself throughout the profession.

Since the year 1868 he had acted as physician to the Royal Society of Musicians. In religion, whilst liberal towards those who differed from him, he was a decided Churchman of the Broad Church school. For many years he was churchwarden to the late Rev. Harry Jones, with whom he was on terms of intimate friendship. Dr. Potter was fond of books, especially of topographical works, and was a great student of Old London. For another part of England he displayed quite a peculiar affection—namely, the West; but his favourite place was Lyme Regis, to which he resorted for his annual holiday for something like 26 years with only one exception.

Dr. Potter married in 1872 Celina, second daughter of Mr. Alfred Blyth of Westbourne-terrace, by whom he had three children—one son, Mr. John Wagner Potter, of the staff of the office of the Crown Agents for the Colonies, and two daughters.

PROFESSOR POTAIN.

THE medical profession of France has been of late sorely tried by the deaths of some of its most prominent members. Foremost among them stands the venerated name of Potain. The aged professor died quite suddenly on Jan. 5th at the age of 75 years. Scarcely six months ago he delivered his last lecture at the Charity Hospital amid an exhibition of enthusiasm and affection which has rarely been equalled and of which a touching description was given by our Paris

correspondent.[1] There, in the presence of the leaders of the French medical profession such as Bouchard, Dieulafoy, Guyon, Déjerine, Marey, Tessier, and many others, surrounded by present and former pupils, and supported by colleagues and friends, the venerable professor spoke for the last time in an official capacity. Very dramatic was the end. 11 o'clock struck, the master stopped and said simply: "Gentlemen, I have given my last lecture; I wish to say a word or two in memory of Corvisart who, 100 years ago, in this very theatre created the first course of clinical medicine in France. I wish to thank my colleagues, my pupils, my friends——." Here he broke off with his eyes full of tears. Those who knew him well feared that the profound change in his way of life which followed his retirement, owing to his having to give up his course of lectures and his daily visit to the hospital, a visit which he never failed for 30 years to make at eight o'clock in the morning, would have a disastrous effect upon the remainder of his life; and such was the case. He became melancholy and oppressed although his bodily health remained good. On Jan. 4th he complained of feeling tired, but paid a visit to Dr. Napias, the head of the Assistance Publique, who was suffering from influenza. He passed a quiet evening in company with Dr. Tessier, his old *chef de clinique*, and went to bed about 11 o'clock. At 2 A.M. on Saturday, Jan. 5th, his servant went into his room to make up the fire and found him dead and cold.

Outside his scientific attainments Professor Potain will be remembered as a typical example of a good and kindly man, one of a fashion now almost passed away, the *vir bonus, medendi peritus*, and as one who took the highest place in his class. A bachelor, with no relatives but one sister, he was, indeed, a father to his pupils. He "sustained" his thesis in 1853, the subject being the Abnormal Bruits which follow Hæmorrhage. Shortly afterwards he became *chef de clinique* to Bouillaud and was successively nominated as physician to the hospitals in 1859 and *professeur agrégé* at the Paris Faculty of Medicine. In 1860 he became physician to the Menages Infirmary, in 1865 physician to the St. Antoine Hospital, and in 1866 to the Necker Hospital. On March 20th, 1875, he was nominated professor of pathology at the Faculty of Medicine and shortly afterwards professor of clinical medicine. In fulfilment of the duties of the last post he lectured in the theatre of the Charity Hospital where Corvisart and Bouillaud had lectured before him, and on the day of his retirement his pupils presented him with the chair from which his two illustrious predecessors and himself had for so long held forth. He was a Member of the Academy of Medicine, a Member of the Academy of Sciences, and Commander of the Legion of Honour. He wrote much, and among his works may be mentioned his lectures on Clinical Medicine and his treatises on Diseases of the Heart, a work of world-wide renown. His funeral, which took place on Jan. 8th, was attended by an enormous crowd, but in accordance with his specially expressed wishes no funeral oration was pronounced over his remains.

JAMES HOUGH, F.R.C.S. ENG., J.P.

WE regret to announce the death of Mr. James Hough, of Grange-road, Cambridge, a venerable practitioner who had been resident in the town for nearly 60 years and occupied a very prominent position amongst its public men. His last illness was of short duration. About six weeks ago he attended the annual meeting of the Cambridge Female Refuge, of which he was the treasurer. Shortly afterwards he suffered from a carbuncle; symptoms of alarming prostration set in, and he passed away quietly on the morning of Dec. 28th, 1900.

Mr. Hough was born on Jan. 19th, 1818, at Palamcottah in India, where his father, the Rev. James Hough, was military chaplain. His mother was Elizabeth Pattinson, third daughter of Thomas and Mary Pattinson, of Kirklinton, Cumberland, and it was to their care that Mrs. Hough entrusted her boy when his parents returned to India after visiting England in 1823. Mr. Hough spent his younger days at Kirklinton and Houghton. His school days were passed at Christ's Hospital; he then studied medicine at Guy's and St. Thomas's Hospitals, and was admitted a member of the Royal College of Surgeons of England in 1841, at the age of 23 years. He became a Licentiate of the Society of Apothecaries in the same year and a Fellow of the Royal College of Surgeons of England in 1876. He commenced his long and appreciated connexion with Cambridge immediately upon becoming qualified, going there as assistant to Dr. Fawcett, with whom he shortly afterwards entered into partnership. This link continued until 1882, when Dr. Fawcett retired. Mr. Hough then took his eldest son, Mr. James Hayward Hough, into partnership and the practice was carried on by father and son until 1893, when the latter died. This bereavement was a great blow to Mr. Hough, and left its effects upon him. In January, 1894, Dr. E. Lloyd Jones joined the firm and remained in partnership with Mr. Hough until 1896 when Mr. Hough retired at the age of 80 years. To the men of the younger generation the deceased was a practitioner of the old school, an all-round man of a kind which the old methods of training were wont to beget. He was well known during the best years of his life as *the* accoucheur at Cambridge. For his practical skill he was no less distinguished than for a tender heartedness which was quite unique. More than half a century of active practice seemed to have lessened in no degree the warm-hearted sympathy with the sick which was one of his greatest characteristics. His emotion was ofttimes but ill-concealed when he saw others suffering. His energy was phenomenal until the very last; to render assistance to the sick, rich or poor, to work for many philanthropic societies or for his political party—these were the ways in which his long and useful life was spent

Mr. Hough had a very active public life. A strong and consistent Conservative, he was long the respected leader of his party at Cambridge. In 1886 occasion was sought to testify to the appreciation of these services felt by his Conservative friends, and on April 18th, at a large and enthusiastic meeting, he was presented with a "buggy," or hooded trap, which became as familiar in the streets of Cambridge as was his own figure. The presentation was made by the Rev. George Forrest Browne, now the Bishop of Bristol, in a most felicitous speech. Mr. Hough occupied the position of chairman of the consultative council and leader of the Conservative party in Cambridge from 1884 to 1899 during which time four contested elections were fought, the result being an "unbroken record" of success for Sir Robert Penrose FitzGerald, the Conservative champion. In October, 1899, he was presented with an illuminated copy of a resolution expressing the indebtedness of the party to him for his services.

Mr. Hough also found time for a considerable amount of Church work, for which his family associations gave him a special aptitude. His father, as has already been mentioned, was a clergyman of the Church of England, and one of his ancestors had been a bishop. Mr. James Hough was churchwarden of St. Benedict's Church from 1848 to 1893. During that period he successfully resisted an attempt to close the church and amalgamate the parish with another, and eventually had the satisfaction of seeing the ancient building beautifully restored. "The Architectural History of the University of Cambridge and of the Colleges of Cambridge and Eton" and a purse of £40 were presented to him by the parishioners and congregation upon his retirement. Mr. Hough had also assisted in the missionary and social work of the Church. He had been treasurer of the local auxiliary of the Church Missionary Society since 1858, and of the Cambridge Female Refuge, and held a like position in connexion with the Cambridge Book Hawking Society from 1857 until it was given up in 1890. He was president of the Cambridge branch of the Church of England Young Men's Society and of the Cottage Orphan Home for Little Girls, and was also warmly interested in the Church Defence Society and the Society for the Propagation of the Gospel. He was moreover chairman of the *Cambridge Express* Newspaper Company from its formation.

Mr. Hough married on July 8th, 1846, Eliza Sophia, daughter of Mr. W. W. Hayward of Cambridge, who died in June, 1893. His family consisted of four sons and four daughters, of whom three sons and two daughters are living. Mr. George Frederick Hough is vicar of Holy Trinity, Worcester, Mr. Charles Henry Hough is a surgeon at Derby, and Mr. William Woodcock Hough is in holy orders and was officiating as the missioner of the Corpus Christi College Mission in London until he resigned through ill-health. Mr. Hough's funeral took place at Mill-road Cemetery, Cambridge, on Jan. 2nd, 1901, and was a

[1] THE LANCET, July 14th, 1900, p. 138.

touching farewell to one whose whole life had been unselfishly devoted to the promotion of good works. The large attendance marked the respect in which the deceased was held, and the difference of classes and opinions represented pointed to the variety of the work in which he had been engaged.

SIR WILLIAM HICKS FARRINGTON, BART., M.D. ST. AND., M R.C.S. ENG., L.S.A.

SIR WILLIAM HICKS FARRINGTON, who was the fifth baronet of his line, was the elder surviving son of the fourth baronet, Sir Henry Anthony Farrington, who died in 1888. Sir William Farrington, who was born in 1838, was educated at the King's School, Ottery St. Mary, and at St. Bartholomew's Hospital, where he held the offices of house surgeon and resident accoucheur. He became a Member of the Royal College of Surgeons of England in 1859 and a Licentiate of the Society of Apothecaries in 1860. Besides his hospital appointments he held those of resident medical officer to the London Fever Hospital and of assistant surgeon to H.M. Convict Prison at Gibraltar. He was afterwards in practice at Penshurst, Kent. He is succeeded in the title by his son Henry Anthony Farrington, who was born in 1871.

CHARLES HARWOOD, M.D., L.R.C.S. EDIN.

DR. CHARLES HARWOOD of Hemington, Leicestershire, died very suddenly on Jan. 3rd while engaged on professional business at some distance from his home. On Jan. 2nd he was apparently in good health and spirits, and on Jan. 3rd he drove to Melbourne, a small town in the adjoining county of Derby, where he was seized with illness while in the house of a member of the board of guardians and expired almost immediately. Dr. Harwood was the son of a medical practitioner in Derby and received his professional education in Edinburgh, where he took the degree of M.D. and the diploma of L.R.C.S. in 1850. At the time of his death he held the appointments of medical officer of health of the Shardlow, Stapleford, and Castle Donington rural district councils; he had also formerly been medical officer of health of the borough of Derby, surgeon to the Derby Dispensary, and surgeon-major to the Derbyshire Regiment. Dr. Harwood was well known and much respected in the Castle Donington district, where he had practised for many years. He has left a widow and family for whom much sympathy is felt.

DEATHS OF EMINENT FOREIGN MEDICAL MEN.—The deaths of the following eminent foreign medical men are announced:—Dr. Horace Tracy Hanks, Professor of Gynæcology in the Post-Graduate Medical School, New York.—Dr. R. J. Curtiss, formerly Professor of Bacteriology in the College of Physicians and Surgeons, Chicago.—Dr. Berne, Honorary Professor in the Medical Faculty of the University of Lyons.

THE WAR IN SOUTH AFRICA.

THE X RAYS IN SOUTH AFRICA.

BY JOHN HALL-EDWARDS, L.R.C.P. EDIN.
SURGEON RADIOGRAPHER TO THE GENERAL HOSPITAL, BIRMINGHAM, AND TO THE IMPERIAL YEOMANRY HOSPITAL, DEELFONTEIN, SOUTH AFRICA.

SOME time before leaving England and long before I had any idea that my services would be required in South Africa I advocated, through the medium of the medical press, a more extended application of the x rays to military surgery. Nine months' experience here has proved that they are much more useful than I even ventured to predict and that in their usefulness they stand only second in importance to aseptic surgery. As my suggestions and predictions then were based purely upon work carried on in civil practice, with but a very superficial knowledge of the actualities of war, I am doubly pleased to record that my hopes have been more than realised and that excellent surgery has been the outcome of the work done here.

Before being appointed on the staff of the Imperial Yeomanry Hospital I made repeated applications to the War Office, always with the same result—viz., a sheet of blue paper informing me that there was no call for x-ray experts in South Africa. On one occasion I had a personal interview with an official at the War Office who told me that for several reasons they could not send me out. In the first place, there was very little useful work to be done; in the second place, that there were already out many men capable of undertaking the work; and lastly, that they could not afford to send me out, however much they might wish to do so. At the same time, I was shown a cablegram from South Africa demanding the immediate presence of eight men with a sufficient knowledge of electricity and photography to enable them to help the experts (?) already sent out and to repair broken-down apparatus—or, in other words, to do the work for which someone else would get the credit. How the arrangement has worked I am not entirely in a position to say, but from what I have heard the results which were produced have not fulfilled the anticipations and expectations of some of the surgeons, and judging from the several cases sent to us where others have failed to find bullets (after the application of the x rays) I should imagine that the experiment has not altogether proved a success. An eminent consulting surgeon who visited our hospital amused me by asking if localisation in my hands had proved a success and I learned from him that in some of the base hospitals the surgeons had been greatly misled by it. On my informing him that a properly carried-out localisation was absolutely accurate and certain he expressed great surprise, proving that he had received some information to the contrary. Granting that the procedure of localisation has been properly carried out, if there is any mistake it is due to want of knowledge on the part of the x-ray operator, who must, if his deductions are to be of any value, have had considerable experience, combined with a knowledge of anatomy and surgery. The assistants sent out by the War Office have in most instances become masters, either from force of circumstances or from a lack of interest on the part of those whom they were sent to assist. I may mention that the experts (?) themselves had in many instances but a few days' training prior to their proceeding to the seat of war. And the work done by their (so-called) assistants may be, and in all probability is, good, but inasmuch as they can have had but a very limited experience, and as in most cases they have no knowledge of anatomy or surgery, the operative surgeons cannot accept any suggestion from them, hence failure results. As an example of the way in which an excellent radiograph and localisation may be misleading I would like to quote the following case which was brought to my notice at a large hospital at Pretoria. A patient having a bullet in his thigh was radiographed and its position was marked on the limb. The surgeon cut down upon the spot indicated but failed to find it; after a prolonged search it was eventually found two inches higher up the limb. It was subsequently found that the spot indicated upon the skin of the patient had been arrived at from measurements made upon the negative. As in every negative there is a small amount of distortion, and in some a very considerable amount, measurements made in this manner are always unreliable and grave consequences are almost certain to follow such an unscientific proceeding.

Notwithstanding the fact that the penetrative power of modern small-bore projectiles is such that at all ranges up to 1500 yards under ordinary circumstances they pass through the tissues without doing any considerable amount of harm, there is in a large war such as we are at present engaged in plenty of work for the surgeon radiographer. Out of the 200 cases which up to the present have come under my notice over 60 bullets or portions of bullets or shells have been found and accurately located. In 54 of these cases the foreign bodies have been removed and in no case has the surgeon failed to find what he looked for. In the remaining cases no operation has been performed, it being thought best—for a variety of reasons it is not necessary for me to mention here—at any rate for the present to leave them undisturbed. Of the remaining 140 cases most of them were examined for the purpose of ascertaining the amount of injury sustained by bone after the passage of a bullet through it, and in a few no foreign body was found, although its presence was suspected.

These figures plainly show that at any rate one of the assertions made by the authorities at home has no foundation in fact and that they formed erroneous opinions, founded on inexperience, as to the numerous accidents which tend to diminish the penetrative power of modern projectiles.

Whilst the capability of the x rays of discovering and accurately locating bullets was not for one moment questioned, the number of bullets which experience has shown are for one reason or another retained in the tissues was vastly under-estimated. At any range up to 1000 yards a Mauser or Lee-Metford bullet will pass through the densest bony structures of the human body, granting that a full charge of cordite has been used, that the bullet has been unimpeded in its flight, and that the cupro-nickel casing is complete. It occasionally happens, however, that a full charge of cordite has for some reason or another not been used. It is still more common for a bullet to strike some hard substance before finding its final billet, and I have good reasons for suspecting that most of those which I have localised come under this category. A ricochet bullet is by far the most dangerous to meet, and the Boers are so far aware of this fact that they prefer to fire low, at the ground, in front of our troops. A ricochet bullet is especially dangerous for three reasons. In the first place, even if it falls upon soft ground and is not deformed, its penetrative power is so greatly diminished that it is likely to be retained in the tissues if it finds a billet; secondly, if it strikes a hard substance it is so altered in shape that serious tearings of the tissues and splintering of bones are certain to accrue; and thirdly, without being greatly altered in shape it may have imparted to it an amount of spin which produces serious results. A spinning bullet is one of the most dangerous of missiles and the amount of damage it is capable of inflicting depends to a very great extent upon the rate of spin; this may be so slow that the entrance wound may present all the characteristics of an ordinary entrance wound, or it may be so fast as to produce a large irregular wound, such as one would expect to have been caused by a piece of shell. Considerable difference of opinion exists as to the possibility of an uninjured Lee-Metford or Mauser bullet being flattened against bone when fired directly into the tissues. From my experience I am of opinion that under such conditions no flattening of the bullet is possible, and that in all cases where a whole bullet is found to be deformed it has struck some substance harder than bone before entering the body.

Quite apart from the finding and localising of bullets, most excellent and useful work is to be done in radiographing all bullet and shell injuries to bone, and many useful observations will be made by the careful examination of the resulting pictures. Our knowledge of the amount and character of injury which under varying circumstances can be done by a bullet, is so small and incomplete that many new facts should come to light as the result of the work done during the present war, and had the x-ray work been as carefully carried out as its importance warrants one of the greatest advances ever made in military surgery would have been placed to our credit. That the x rays have not been given a fair chance I am in a position to prove. Some hospitals have been supplied with excellent apparatus but no one to work it, whilst in others there is no apparatus, and in a few, whilst having the apparatus, it is placed in such incompetent hands as to prove rather a source of danger than one of the most useful adjuncts. Many patients have been sent home with bullets still in their tissues which should have been removed, whilst others have suffered weeks of pain which should have been relieved in a few hours.

If the x rays are to prove of full use in future wars one of the first steps to be taken by our War Office must be the organisation of a complete x ray department, where the methods of procedure will be properly taught, experiments made, and apparatus designed and manufactured, with a full knowledge of the requirements of military surgery under all conditions and circumstances. The apparatus placed at my disposal is as complete and efficient as could be purchased. Nevertheless, it is by no means perfect, and had I been placed in less fortunate circumstances I should several times have been landed in difficulties. Experience has convinced me that much time and thought will have to be expended before our apparatus can even be said to be as perfect as our present knowledge will allow, and as the science is certain to progress there is a large field open to experiment. It would be greatly to the advantage of the Army Medical Department if experiments were carried out under their own control. The cost would be but a trifle compared with the great advantages which would be reaped not only to military but to civil surgery.

In future wars each base hospital must have its surgeon-radiographer, and in addition there must be a number of experts unattached who with portable apparatus can be sent anywhere and everywhere as circumstances may demand. Several lives and limbs would have been saved during the present war—for instance, at the relief of Mafeking—had an expert been within reasonable call. Inasmuch as radiography has been recognised as a legitimate branch of medicine none but qualified experts should be employed, and apart from this, and for reasons which I have already mentioned, this is absolutely necessary if the best results are to be sought after. Recent events at home have shown that the x rays in inexperienced hands are a source of great public danger, and it is to be hoped that steps will be taken to place it beyond the power of the novice to expose his friends or enemies to danger.

In this letter I have purposely refrained from entering into details of any of the many interesting cases which have passed through my hands; I hope, however, to publish some of these on my return home.

Deelfontein, South Africa.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN 33 of the largest English towns 7329 births and 3964 deaths were registered during the week ending Jan. 5th. The annual rate of mortality in these towns, which had been 16·1 and 16·9 per 1000 in the two preceding weeks, further rose last week to 17·5. In London the rate was 17·8 per 1000, while it averaged 17·3 in the 32 large provincial towns. The lowest death-rates in these towns were 8·6 in Derby, 10·5 in Croydon, 11·2 in Norwich, and 12·0 in Portsmouth; the highest rates were 21·0 in Birkenhead, 21·4 in Sheffield, 21·5 in Manchester, and 22·5 in Liverpool. The 3964 deaths in the 33 towns last week included 323 which were referred to the principal zymotic diseases, against 351 and 334 in the two preceding weeks; of these 79 resulted from diphtheria, 71 from whooping-cough, 56 from measles, 47 from "fever" (principally enteric), 37 from diarrhœa, and 33 from scarlet fever. No death from any of these diseases occurred last week in Huddersfield; in the other towns they caused the lowest death-rates in Cardiff, Burnley, Hull, and Newcastle, and the highest rates in Wolverhampton, Salford, Blackburn, and Sheffield. The greatest mortality from measles occurred in Wolverhampton and in Blackburn; and from whooping-cough in Birkenhead and Sheffield. The mortality from scarlet fever and from "fever" showed no marked excess in any of the large towns. The 79 deaths from diphtheria included 24 in London, eight in West Ham, eight in Sheffield, seven in Leicester, and five in Bristol. No fatal case of small-pox was registered last week in any of the 33 towns, and only one small-pox patient remained under treatment in the Metropolitan Asylums hospitals on Saturday last, Jan. 5th. The number of scarlet fever patients in these hospitals and in the London Fever Hospital at the end of the week was 2390, against 2477 and 2535 on the two preceding Saturdays; 163 new cases were admitted during the week, against 255, 218, and 167 in the three preceding weeks. The deaths referred to diseases of the respiratory organs in London, which had been 306 and 325 in the two preceding weeks, further rose last week to 330, but were 376 below the corrected average. The causes of 49, or 1·3 per cent., of the deaths in the 33 towns last week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in Nottingham, Bradford, Leeds, and in 12 other smaller towns; the largest proportions of uncertified deaths were registered in Liverpool, Preston, Hull, and Gateshead.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in the eight Scotch towns, which had been 18·2 and 20·6 per 1000 in the two preceding weeks, declined again to 19·2 during the week ending Jan. 5th, but showed an excess of 1·7 per 1000 over the mean rate during the same period in the 33 large English towns. The rates in the eight Scotch towns ranged from 14·4 in Paisley and 15·7 in Leith to 21·5 in Edinburgh and in Dundee and 22·4 in Greenock. The 602 deaths in these

towns included 29 which were referred to whooping-cough, 22 to diarrhœa, 15 to measles, three to small-pox, three to diphtheria, two to scarlet fever, and two to "fever." In all, 76 deaths resulted from these principal zymotic diseases, against 74 and 87 in the two preceding weeks. These 76 deaths were equal to an annual rate of 2·4 per 1000, which was 1·0 above the mean rate last week from the same diseases in the 33 large English towns. The fatal cases of whooping-cough, which had been 26 and 33 in the two preceding weeks, declined again last week to 29, of which 16 occurred in Glasgow, five in Greenock, four in Dundee, and three in Edinburgh. The deaths from diarrhœa, which had increased from 10 to 18 in the three preceding weeks, further rose to 22 last week, and included seven in Glasgow, seven in Dundee, and four in Aberdeen. The fatal cases of measles, which had been 12 in each of the two preceding weeks, increased last week to 15 of which 12 were registered in Edinburgh and two in Aberdeen. The three deaths from small-pox corresponded with the number in the preceding week, and were all recorded in Glasgow, where two of the three fatal cases of diphtheria and both of the deaths from "fever" were also registered. The deaths referred to diseases of the respiratory organs in these towns, which had been 111 and 121 in the two preceding weeks, declined again last week to 105, and were 131 below the number in the corresponding period of last year. The causes of 38, or nearly 6 per cent., of the deaths in these eight towns last week were not certified.

HEALTH OF DUBLIN

The annual rate of mortality in Dublin, which had declined from 27·4 to 21·5 in the four preceding weeks, rose again to 29·4 during the week ending Jan. 5th. During the past four weeks the death-rate in the city has averaged 25·6 per 1000, the rate during the same period being 16·7 in London and 18·5 in Edinburgh. The 197 deaths belonging to Dublin registered during the week under notice were 53 in excess of the number in the preceding week and included 23 which were referred to the principal zymotic diseases, against 16 and 12 in the two preceding weeks; of these, 13 resulted from whooping-cough, four from diphtheria, three from "fever," two from measles, and one from diarrhœa. These 23 deaths were equal to an annual rate of 3·4 per 1000, the zymotic death-rate during the same period being 1·2 in London and 3·2 in Edinburgh. The fatal cases of whooping-cough, which had been seven, six, and five in the three preceding weeks, increased last week to 13. The four deaths from diphtheria exceeded the number recorded in any week since February last. The fatal cases of "fever" which had been four in each of the two preceding weeks, declined to three last week. The 197 deaths in Dublin last week included 48 of children under one year of age and 47 of persons aged upwards of 60 years; the deaths of infants were largely in excess, while those of elderly persons corresponded with the number in the preceding week. Three inquest cases and three deaths from violence were registered, and 53, or more than one-fourth, of the deaths occurred in public institutions. The causes of 17, or nearly 9 per cent., of the deaths in the city last week were not certified.

VITAL STATISTICS OF LONDON DURING DECEMBER, 1900.

IN the accompanying table will be found summarised complete statistics relating to sickness and mortality in each of the 43 sanitary areas of London. With regard to the notified cases of infectious diseases it appears that the number of persons reported to be suffering from one or other of the nine diseases specified in the table was equal to an annual rate of 8·0 per 1000 of the population, estimated at 4,589,129 persons in the middle of last year. In the three preceding months the rates had been 8·7, 10·7, and 10·0 per 1000 respectively. The rates were considerably below the average in St. George Hanover-square, Hampstead, Holborn, Clerkenwell, St. George-in-the-East, and Lee; while they showed the largest excess in Fulham, Stoke Newington, Shoreditch, Poplar, St. Saviour Southwark, and St. George Southwark sanitary areas. No case of small-pox was notified last month, and only one small-pox patient remained under treatment in the Metropolitan Asylums hospitals on Saturday, Dec. 29th. Scarlet fever was considerably less prevalent than it had been in any of the three preceding months; among the various sanitary areas this disease showed the greatest proportional prevalence in Fulham, St. James Westminster, Stoke Newington, Strand, Greenwich, and Lewisham (excluding Penge). The Metropolitan Asylums hospitals contained 2460 scarlet fever patients at the end of December, against 1899, 2569, and 2659 at the end of the three preceding months; the weekly admissions averaged 214, against 215, 314, and 259 in the three preceding months. The prevalence of diphtheria showed a considerable decline from that recorded in the preceding month; the greatest proportional prevalence of this disease occurred in Fulham, Stoke Newington, Shoreditch, Poplar, St. Saviour Southwark, and St. George Southwark sanitary areas. There were 1343 diphtheria patients under treatment in the Metropolitan Asylums hospitals at the end of last month, against 1231, 1458, and 1524 at the end of the three preceding months; the weekly admissions averaged 157, against 185, 206, and 185 in the three preceding months. The prevalence of enteric fever showed a decrease from that recorded in recent months; among the various sanitary areas this disease was proportionally most prevalent in St. Marylebone, St. Pancras, City of London, St. Olave Southwark, Camberwell, and Plumstead. The number of enteric fever patients in the Metropolitan Asylums hospitals, which had been 329, 444, and 436 at the end of the three preceding months, had further declined to 403 at the end of December; the weekly admissions averaged 51, against 61 in each of the two preceding months. Erysipelas was proportionally most prevalent in Westminster, Stoke Newington, St. Giles, St. Luke, Whitechapel, and Limehouse sanitary areas. The 19 cases of puerperal fever included three in Islington, two in Paddington, two in Poplar, and two in Wandsworth sanitary areas.

The mortality statistics in the table relate to the deaths of persons actually belonging to the various sanitary areas of the metropolis, the deaths occurring in the public institutions of London having been distributed among the various sanitary areas in which the patients had previously resided. During the four weeks ending Dec. 29th the deaths of 5687 persons belonging to London were registered, equal to an annual rate of 16·2 per 1000, against 16·5, 15·3, and 16·8 in the three preceding months. The lowest death-rates last month in the various sanitary areas were 10·2 in City of London, 11·0 in St. Martin-in-the-Fields, 11·6 in Hampstead, 11·7 in Stoke Newington, 12·0 in St. Giles, and 12·2 in St. James Westminster; the highest rates were 20·6 in Shoreditch, 21·3 in St. Saviour Southwark and in St. George Southwark, 21·7 in Poplar, 22·3 in Bermondsey, and 23·4 in Rotherhithe. During the four weeks of December 478 deaths were referred to the principal zymotic diseases; of these, 95 resulted from measles, 30 from scarlet fever, 114 from diphtheria, 115 from whooping-cough, 78 from enteric fever, and 46 from diarrhœa. No death from any of these diseases occurred last month in Holborn or in Woolwich; in the other sanitary areas they caused the lowest death-rates in St. George Hanover-square, Westminster, Whitechapel, and St. George-in-the-East; and the highest rates in St. Martin-in-the-Fields, Shoreditch, Poplar, St. Saviour Southwark, Bermondsey, and Rotherhithe. The 95 deaths from measles showed a decline of 170 from the corrected average number; this disease was proportionally most fatal in St. Luke, Shoreditch, St. George Southwark, Bermondsey, Battersea, and Lewisham sanitary areas. The 30 fatal cases of scarlet fever were 46 below the average number in the corresponding periods of the 10 preceding years; the greatest proportional mortality from this disease occurred in Hammersmith, Fulham, St. Marylebone, St. Giles, Strand, and City of London sanitary areas. The 114 deaths from diphtheria showed a decline of 104 from the corrected average number; among the various sanitary areas this disease was proportionally most fatal in Paddington, Stoke Newington, Shoreditch, Poplar, St. Saviour Southwark, and Rotherhithe. The 115 fatal cases of whooping-cough were 57 below the average number in the corresponding periods of the 10 preceding years; this disease showed the highest proportional fatality in Kensington, Hampstead, Strand, St. George Southwark, Rotherhithe, and Battersea sanitary areas. The 78 deaths referred to enteric fever were slightly in excess of the corrected average; among the various sanitary areas the death-rate from this disease was highest in Hammersmith, St. James Westminster, St. Martin-in-the-Fields, Strand, City of London, and St. Saviour Southwark. The 46 fatal cases of diarrhœa were below the average number in the corresponding periods of the

ANALYSIS OF SICKNESS AND MORTALITY STATISTICS IN LONDON DURING DECEMBER, 1900.

* Including 22 cases of membranous croup.

† Including deaths from membranous croup.

NOTE.—The changes made under the London Government Act (1899) are not taken into account in the above table.

10 preceding years; this disease was proportionally most fatal in Hammersmith, Westminster, St. Giles, St. Martin-in-the-Fields, Bermondsey, and Lee. In conclusion, it may be stated that the aggregate mortality from these principal zymotic diseases in London during December was more than 43 per cent. below the average.

Infant mortality in London last month, measured by the proportion of deaths of children under one year of age to registered births, was equal to 164 per 1000. The lowest rates of infant mortality were recorded in Stoke Newington, St. Giles, Clerkenwell, St. Luke, City of London, and Whitechapel; and the highest rates in Kensington, Hammersmith, St. Martin-in-the-Fields, St. Saviour Southwark, St. George Southwark, and Rotherhithe sanitary areas.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

THE following appointments are notified:—Fleet Surgeon A. Patterson to the *Blake;* Surgeon R. A. Kirby to the *Blake*. Deputy Inspector-General Evelyn R. H. Pollard relieves Deputy Inspector-General Richard Coppinger at Jamaica Hospital.

ROYAL ARMY MEDICAL CORPS.

Major Lane is transferred from the Scinde District to the Bombay District and is appointed to the medical charge of the Station Hospital, Deolali. Major A. E. Morris is appointed to the medical charge of the Station Hospital, Hyderabad (Scinde). Major W. Babtie, V.C., C.M.G., is appointed to the Home District for temporary duty. Captain G. A. Moore is posted to the Station Hospital, Shorncliffe, for duty.

ARMY MEDICAL RESERVE OF OFFICERS.

Surgeon-Captain A. G. Bateman, having resigned his Volunteer appointment, ceases to belong to the Army Medical Reserve of Officers. Surgeon-Captain Evan Evans to be Surgeon-Major.

YEOMANRY CAVALRY.

Herts: Surgeon-Lieutenant J. A. Turner resigns his commission.

TRANSVAAL WAR NOTES.

Civil Surgeon J. W. Aldred died at Kroonstad on Jan. 1st from enteric fever.

The following have been discharged from hospital to duty:—Surgeon-Lieutenant J. C. J. MacNab, 1st Fifeshire Volunteer Artillery; Captain C. F. Wanhill, Captain F. J. Wade-Brown, and Lieutenant W. J. Padye-Curran, and Civil Surgeons C. H. Pegg, E. H. North, J. G. Martin, and A. W. Saunders, Royal Army Medical Corps.

The *Norman* left for England on Dec. 27th, having on board Civil Surgeon H. R. Phillips.

Viscountess Parker, president of the Ladies' Committee of the Welsh Hospital, has received a letter from the Queen with reference to the report recently issued by the committee on the work of the hospital in South Africa. Her Majesty expresses her gratitude for the admirable work done by the hospital and grieves for the loss of the valuable lives among its staff in the fulfilment of their noble, self-sacrificing work.

The *Arundel Castle* left for England on Jan. 1st, having on board Civil Surgeons W. J. Waters, P. Wood, and C. C. Simpson.

The following officers of the Royal Army Medical Corps will retire during the present year: Colonel C. F. Churchill on April 10th; Colonel R. H. Carew, D.S.O., on August 10th; Lieutenant-Colonel H. H. Stokes on Sept. 11th; Surgeon-General H. S. Muir on Oct. 4th; and Surgeon-General T. F. O'Dwyer on Dec. 26th.

THE ARMY MEDICAL SERVICE OF JAPAN.

It is almost a platitude to say that the Japanese are a most intelligent, enterprising, and progressive people, for the fact has long been recognised. It is not that they are remarkable merely for their receptive and imitative faculties, for Eastern peoples are often that, but the Japanese possess, in addition to a singular aptitude for mastering details, constructive and initiative powers as well as considerable mental and physical energy. With these qualities, together with great natural courage, they are the born leaders of the yellow race and are probably destined to play an important part in history. It is not only in the organisation and equipment of their naval and military forces, but in the part they are taking in scientific research, and especially in medical science, that the Japanese have already made their mark, as indicated in Kitasato's discovery of the plague bacillus and in his new method of treating dysentery by serum inoculation. In the practice of the art of surgery, as might have been expected from a people who have exhibited so much manipulative skill and delicacy and attention to detail and minutiæ in their weird artistic productions, they excel. During the war with China in 1894–95 it will be remembered that the present Surgeon-General Taylor of the British Army Medical Service accompanied the Japanese forces in the field, and that on his return he wrote in his official report in high terms of praise of their medical organisation and arrangements during that campaign. The impression which we then formed was that if they were lacking in anything it was in applied army hygiene. The Japanese being an eminently teachable people, however, lost no time in turning the experience they gained in their war with China to account, and they have made all their hospital arrangements for the present war in that country, in which they are taking part, in common with the forces of the European Powers and America, on a very comprehensive and elaborate scale and practically with marked success. In the *Times* of Jan. 7th there is a most interesting communication from its correspondent at Tokio on the "Army Medical Service in Japan" which is well worth reading at the present time. When it is considered that Japan on the present occasion is put in comparison and competition with all the other armed powers operating in China, the result is remarkable and highly creditable to the Japanese Government. From all we have heard the German hospital arrangements in China are very good and the same may be said of the British, Americans, and Japanese, but what might not have been expected is that those of the last-named should have been as complete and excellent as they undoubtedly are.

THE CIRCULAR LETTER FROM THE DUKE OF CAMBRIDGE.

Our readers have probably perused for themselves the circular letter which the President of the Patriotic Fund has addressed to the municipal and county authorities throughout the United Kingdom. Its object apparently is to nationalise all the systems and charitable institutions at present in operation for the relief of sufferers by the war, and to organise a network of local associations in regular communication with a central council—the Commissioners of the Patriotic Fund. Various philanthropic and well-known institutions—the British Red Cross Society, Lloyd's Patriotic Fund, and Trusts for Old and Disabled Soldiers—should be, it is proposed, welded together, consolidated, and merged into one. The proposal seems to be in the abstract and in principle a sound one in that it would prevent a good deal of energy and money from being ineffective or wasted in administration, and do away with much of the existing overlapping of many societies. But the Commissioners of the Patriotic Fund have not somehow managed to obtain the trust and confidence of the nation in respect of the management of that fund. The general public, we imagine, desire to see the money they contribute for compassionate purposes go straight to the objects of their sympathy, and there is a danger, too, lest the charitable contributions to existing and well-known bodies might be seriously checked.

THE TOTAL LOSSES IN SOUTH AFRICA.

According to the War Office returns issued on Jan. 4th, 1901, showing the casualties in the field force in South Africa reported during the month of December, 1900, and total casualties since the beginning of the war up to and including the month, it would appear that during December the casualties were 118 officers and 2306 non-commissioned officers and men. 28 officers were either killed or died of wounds or of accidents or of disease and 750 non-commissioned officers and men from the same causes. The totals up to and including the month show that 421 officers and 4251 non-commissioned officers and men were killed or died of wounds, and 174 of the former (officers) and 7011 men died of disease. The total deaths in South Africa from all causes amounted to 604 officers and 11,554 men, while 1638 officers and 36,988 men were sent home as invalids. The total reduction of the military forces through war in South Africa from all causes, including deaths in that country and among invalids sent home or discharged the service as unfit, together with missing and prisoners, make up a total of 615 officers and 14,265 men, or 14,880 altogether.

A TRIBUTE TO THE ARMY MEDICAL DEPARTMENT.

Brigadier-General T. C. Porter on Dec. 29th received a

hearty welcome from the inhabitants of his native borough of Saltash, Cornwall, upon the occasion of his return from South Africa, and an address was presented to him in the town-hall by the Mayor and town council. In the course of an interesting speech upon the war Brigadier-General Porter said that he could not use the expressions "medical officer" or "chaplain" without a feeling of the deepest reverence, and added that wherever death stood in all its nakedness there was the medical officer or the chaplain, both without a feeling of any sort in their mind except the help which they could offer to the poor unfortunate fellows who then and there required it.

ASSASSINATION OF A MEDICAL OFFICER.

We much regret to announce that a Reuter's telegram from Calcutta, dated Jan. 9th, says that Captain Dudley Cater Johnston, I.M.S. (24th Bombay Infantry), senior medical officer at Loralai, east of Quetta, has been murdered in the civil bazaar by a Ghazi. The assassin was arrested. Captain Johnston qualified in 1891 as M.R.C.S. Eng., L.R.C.P. Lond. The fanaticism of the Ghazis is well known and this is by no means the first occasion upon which the lives of Europeans, both military and civil, have been sacrificed. Captain Johnston who, it will be seen, was a young officer, only entered the Indian Medical Service in 1897, and is thus untimely cut off at almost the threshold of his career.

THE BRITISH RED CROSS SOCIETY.

Lord Wantage, in a letter to the press, detailing the work done by this society, of which he is chairman, states that the total number of persons treated in the wards of the hospital ship *Princess of Wales* has amounted to 725. The Princess Christian hospital train has visited and relieved over 30 hospitals and field stations.

NAVAL MEDICAL SUPPLEMENTAL FUND.

At the quarterly meeting of the directors of the Naval Medical Supplemental Fund held on Jan. 8th Sir J. N. Dick, K.C.B., in the chair, the sum of £70 was distributed among the several applicants.

Correspondence.

"Audi alteram partem."

"ISOLATION HOSPITALS."

To the Editors of THE LANCET.

SIRS,—In THE LANCET of Dec. 29th, p. 1921, Mr. E. D. Marriott replies to my previous letter to you—he does not answer it. Instead of claiming that my chart proved his case I would like Mr Marriott to explain why the notified cases of scarlet fever in Bolton diminished during the years 1889 to 1894, having, of course, first assumed that the increase during 1885 to 1889 was caused by the opening of the isolation hospital in 1884. I presume that the hospital remained open during the entire period under discussion. I would also like Mr. Marriott to explain why the considerable fall of notified cases in Nottingham in 1896 followed the year of the highest percentage of removals. The very high increase of cases in 1899, the rise I am accused of omitting for my own purposes, occurred in a year with an exceptionally small percentage of removals. The fall following the highest percentage of removals known in Nottingham, and the highest number of notified cases following the smallest percentage of removals since 1887 are two facts strongly opposed to Mr. Marriott's inference; they most certainly do not prove his case.

In reference to periodic waves I think the evidence in favour of them is very strong; however, whether such waves exist or not is no proof that scarlet fever should not be aggregated, if we still consider that disease to be infectious. Mr. Marriott states that 93 per cent. (a very high figure) of notified cases are removed to hospital for isolation, and calls this "practically all," and concludes that this aggregation of "practically all" the cases "must succeed in stamping out the disease at no distant date." He then anticipates the future and explains that the reason for this not occurring "will be found in the continued infectivity of hospital discharged patients." He blames the "hospital discharged patients" for the continuance of scarlet fever in our midst; he ignores any mischief that may be caused by the 7 per cent. of infectious cases left at home, and takes absolutely no notice of a very highly important and serious third element—namely, cases that are for various reasons never notified, cases found in the large public and board schools freely desquamating and sowing the disease broadcast over their district. I do not know Mr. Marriott's definition of "return case," but to my mind all the instances he gives in his letter would come within that category.

I am, Sirs yours faithfully,

Manchester, Jan. 5th, 1901. A. J. TONKIN, M.B.R.U.I.

UNIVERSITY COLLEGE, LONDON: RETIREMENT OF THE BEADLE OF THE MEDICAL LIBRARY.

To the Editors of THE LANCET.

SIRS,—Will you kindly allow me an opportunity through your columns of letting old University College men know that Mr. Mann, the beadle of the medical library, has just been pensioned after 37 years' service? He is 80 years of age and in feeble health and it is thought that many who have known him will be glad of an opportunity of helping to make his remaining days as comfortable as possible. Subscriptions may be sent to Mr. Raymond Johnson, University College, London.

I am, Sirs, yours faithfully,

HERBERT R. SPENCER,

Jan. 7th, 1901. Dean of the Medical Faculty.

"THE TREATMENT OF PULMONARY TUBERCULOSIS."

To the Editors of THE LANCET.

SIRS,—Your correspondent "M.R.C.S.," whose letter appeared in THE LANCET of Jan. 5th, p. 66, is, of course, entitled to his own opinion respecting the sanatorium treatment of consumption, though, as it seems to be in opposition to that of nine-tenths of the medical profession of the civilised world, no great importance will be attached to it by your readers. What he is not entitled to do is to cast unwarrantable aspersions upon the motives of those who are engaged in a legitimate branch of practice unsupported by evidence of any kind. I undertake to say, and I speak with knowledge, that the motives of those medical men who are carrying out this system of treatment are as free from commercial taint as those of any other class of practitioner. The life is an arduous one, and presents few attractions apart from the interest of the work itself. The suggestion that non-tuberculous cases are received, and are encouraged to believe themselves to be sufferers from the disease which they have not is simply libellous and absolutely false. I might retort by the suggestion that the serious prejudice of "M.R.C.S." against sanatorium treatment is due to the fact that it involves the withdrawal of profitable patients from the dispensation of their family attendant, but I will not stoop to his methods of controversy. So far from agreeing that the profession has "gone mad" on the subject I contend that we in this country have just come to our right mind about it, as hitherto we have been far behind other nations in this matter.

"M.R.C.S." prophesies that the open-air treatment will in a short time die. Yes, it will die when it has done its work and when consumption has become extinct. Meanwhile there is plenty of work to be done, and the system, being based on common-sense and of approved utility, will survive a good deal of adverse criticism. Sanatorium treatment of chronic diseases is, as Dr. A. H. Carter recently pointed out, much more in accord with modern conceptions than home treatment and is bound to become general. The open-air treatment, not of phthisis only but of many other maladies, has a great future before it and the sneers of "M.R.C.S." are but as dust in the balance when opposed to the reasoned approval of better informed men.

I am, Sirs, yours faithfully,

Jan. 5th, 1901. M.D.

THE LICENTIATE IN DENTISTRY AND THE ADMINISTRATION OF ANÆSTHETICS.

To the Editors of THE LANCET.

SIRS,—In THE LANCET of Jan. 5th (p. 73) there is a note as to a death at Newport (Mon.) after an operation under gas and ether for the extraction of teeth in a young man aged 21

years. It would appear from the words of the report "a medical man was fetched," that no medical man was present at the operation, and that it was performed, and also the anæsthetic administered, by the dental surgeon. Also it seems that though an obstruction to respiration was thought to exist in the throat tracheotomy was not performed. Again, the female attendant stated that she believed she had taken all the sponges from the patient's throat and yet one of them was found post mortem to be fixed in the windpipe.

This case, if it be correct as reported, seems to me to raise the very serious question as to the justification as well as the competence of one person to undertake both the operation and the administration of the anæsthetics. Here apparently we have a dentist who has no medical qualification—and if he had it would make no difference to the issue—undertaking two difficult things, each usually regarded as sufficient to task the attention of one man. The administration of a major anæsthetic for the extraction of teeth is a very serious and responsible matter, as much so as in the case of most ordinary surgical operations. Had a medical man given the anæsthetic, or even been present, the loss of the sponge might have been noticed, and if unnoticed he might have recognised that the obstruction, whatever it was, would be obviated by tracheotomy, which he could have performed. It does not seem to me that an L.D.S. only is competent to deal with the risks and their sequelæ of serious operations *plus* the administration of anæsthetics.

Has a non-medically qualified dentist the legal right, or is he regarded by the college which grants his diploma as competent, to administer a major anæsthetic or, indeed, any anæsthetic at all? The matter is not usually one of emergency, at any rate in the case of a major anæsthetic, and the coroner has nothing to guide him as to these questions.

Dr. Dudley Buxton in his book on Anæsthetics has a paragraph apt to this case. The question, Who is to be regarded as competent to administer an anæsthetic? needs medical and legal regulation and settlement.

I am, Sirs, yours faithfully,

Jan. 5th. Q.

*** We deal editorially this week with some points in this case.—ED. L.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

The Bishop of Calcutta on Physiological Experiment.—The Hospital Ship "Gwalior" and Invalids from China.—The Progress of the Plague: Increase in Bengal.—The Famine.

THE recent utterances of Dr. Welldon, Bishop of Calcutta, may prove of considerable value. Having visited the Pasteur Institute at Kasauli he speaks of the experiments at first hand and says: "I know the process to be characterised in all its aspects by the most thoughtful and scrupulous humanity." His arguments in favour of scientific research seem unanswerable. He refers to the religious as well as the medical side of the question and on the first head quotes Genesis ix. 2, 3. This revelation of faith is without the slightest ambiguity, but the bishop also made use of another excellent argument—that of the principle of vicarious sacrifice. He refers to the awfulness of this law—how it ranges throughout nature and how it enables one species to live at the expense of the lives of others. "Wherever life, even the lowliest, is laid down for the preservation of other lives that principle is seen." Passing from the sanction of religious authority for the fact that man is entitled to take the life of the animal creation for his own, he goes on to say: "and to take it even though the process of taking it is not painless," but whether man acts according to his noblest instincts if he treats the sacrifice of animal life as a mere sport the bishop thinks open to question. Even on this head he holds very broad views and says: "I will say frankly that in my eyes the battle of man with the wild animals is rather an element in that discipline of self-defence in which men by the law of their sex are naturally engaged." Referring to the sacrifice of life which ranges throughout Nature in involuntary ways the argument is extended to show how this involuntary sacrifice passes into the sphere of free volition, from the sacrifice in which no moral element is involved to the sacrifice of the good for the good. The bishop concludes: "But if under the mysterious divine law which constitutes sacrifice the price of human existence and the penalty of human progress man is entitled to take the lives of the animals for his own life, who can doubt that what is true of mere sport is not less true of medical and surgical relief? For these the pain is less and the gain is infinitely greater. There the sacrifice is made, not for a momentary gratification of taste or triumph of skill, but for the immunity of human beings and of the lower animals themselves from the agonies of disease and death."

The hospital ship *Gwalior* has returned from China and disembarked the sick and invalid troops of the various native regiments composing the Indian contingent in China. Soon after her arrival at Hong-Kong the *Gwalior* was despatched to Taku. Having embarked invalids from Peking and Tientsin the vessel called at Wei-hai-Wei. The Maharajah of Gwalior has returned after having served for a brief period on the staff of Sir Alfred Gaselee. We understand that the ship will be again sent to the China station. The transport *India* has also arrived with nearly 1000 sick and weak men from the various native regiments and coolie corps. About 600 men—coolies and followers—were found to be weak in the chest and of poor physique, rendering them unfit to stand the winter climate. On Nov. 20th, at Taku the buckets of water kept on deck were found to be frozen into solid ice. The troops at Peking and elsewhere now are picked and strong men and are accommodated in barracks with fireplaces and a double supply of warm clothing, blankets, &c. The German and French troops are said to be suffering severely. The good health that the Indian contingent is keeping at the present time shows that everything possible is being done for the welfare of our troops.

News relating to plague is this week unsatisfactory. For the whole of India there have been 2107 deaths, as compared with 1989 for the week before and 1685 for the corresponding week of last year. The virulence of the rising epidemic seems to have been translated from the west to the east, the Bombay Presidency showing a decline, while the Bengal province shows a considerable increase. The disease is very rife in Patna (549 deaths this week against 457 last week), Saran (306 against 217), and Monghyr (110 against 74). In the Mysore province, whence 547 deaths are reported, it continues as severe as before. The recrudescence in Bangalore is declared in some quarters to be the result of the new regulations which virtually withdraw almost the whole of the checks previously imposed on the spread of the disease. In Bombay city there is apparently a recrudescence, but the increase is at present small. In Calcutta the disease is slumbering, but the general mortality is unusually high and a large number of suspicious deaths are occurring. The general mortality in Bombay city has again risen and now stands at 898 for the week. Of this number 102 deaths occurred from plague. The births being about the same as last year it is probable that the population is about the same. The curious increase of deaths from phthisis continues. As compared with Calcutta it is important to note that about 40 cases of plague are in the hospitals, whereas there is not a single case in the hospitals in Calcutta.

Inoculation in Bombay city has sunk to practically nothing and in Calcutta there is no sign of any attempt on the part of the authorities or of the people to take advantage, in view of the probable approaching outbreak, of this protection. In Calcutta everything is apparently being sacrificed for the huge experiment of wholesale disinfection. We are informed that over 200,000 rooms, chiefly of the native huts, have been disinfected; in the course of a few weeks almost the whole of the native quarters will have had the ground floors disinfected.

The prospects of the famine in parts of the Deccan in western India are unsatisfactory. Owing to the deficiency of rain in this district again this season the crops have withered. The people are returning to the relief works in increasing numbers as there is no demand for field labour. It is estimated that relief works for at least 80,000 will have to be maintained in that district until the advent of the next monsoon. For the whole of India there are still about 250,000 persons on relief—about two-thirds of this number are engaged on relief works, the remainder receiving gratuitous relief.

Dec. 22nd, 1900.

SURGICAL ANÆSTHESIA BY THE INJECTION OF COCAINE INTO THE LUMBAR SUB-ARACHNOID SPACE.

(FROM A CORRESPONDENT.)

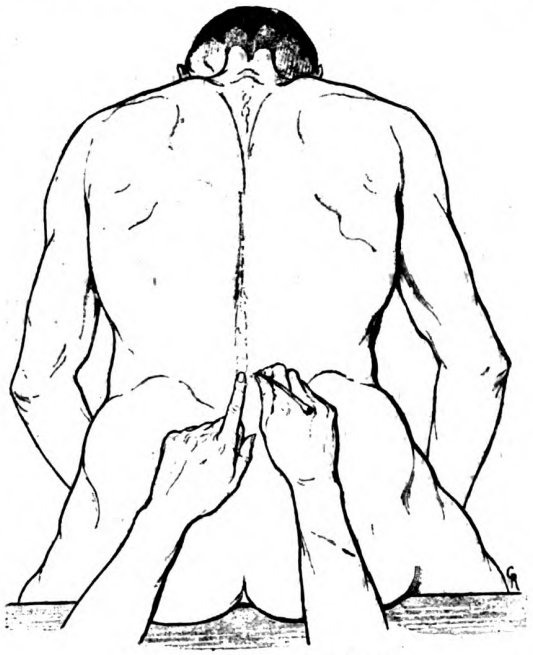
THE event of the late surgical year in Paris has undoubtedly been the impetus given by Tuffier to the method of inducing anæsthesia by medullary injections of cocaine, a suggestion already made and acted upon by Bier of Kiel [1] and Seldowitsch [2] of Russia and Corning of Chicago,[3] but which had left little impress upon current surgical practice or literature. Tuffier's first publication on the subject was made more than one year ago in the *Presse Médicale*, Nov. 15th, 1899, and since then the interest aroused has been abundantly proved by the mass of observations and criticism recorded.

To judge by the most recent *résumé* [4] of the subject one would almost think that the final cry of "Eureka" had been raised and that a general anæsthetic had been found to largely replace chloroform and ether, free from both their dangers and their inconveniences. Here and there, however, a few warning voices have been raised, and it is interesting to note that England, with her characteristic conservative caution, is lagging behind the general movement.

A rapid survey will enable us to pick out the more salient features of the subject, while the readers of THE LANCET will no doubt be interested even in the details of the important points, such as the technique of the injection, the after-consequences and effects of the cocaine, and the nature of the operations in which it has been used. Tuffier was first led to use it as a means of relief in the case of a young man suffering from an inoperable osteo-sarcoma of the ilium whom morphia failed to relieve. The result of the injection of cocaine was striking. The patient, who was crouching down in the position of greatest ease, felt the pain disappear in a few minutes and was even able to rise. There was at the same time absolute anæsthesia reaching to the umbilicus. Unfortunately the relief lasted only a few hours and the injection was repeated two days later with similar effect, pressure over the tumour for some hours causing no pain whatever. A few days later a similar injection was tried for a patient with a recurrent sarcoma of the thigh, and to Tuffier's surprise he was able to remove completely the tumour with absolutely no pain to the patient, the anæsthesia lasting over an hour. At first, therefore, used only in the surgery of the lower limbs, Tuffier rapidly extended its use to operations upon the perineum, the rectum, the anus, the bladder, the ureter, the kidney, and such laparotomies as hysterectomy, removal of the appendix, and even gastro-enterostomy. Finally, removal of the breast has been effected with complete anæsthesia. Convinced of the *absolute harmlessness* of the injections, Tuffier [5] then used them in general gynæcology and performed such operations as hysteropexy, drainage of salpingitis, ovariotomy, vaginal hysterectomy, &c., with equal success. Legueu,[6] however, complains that in one of his three vaginal hysterectomies the anæsthesia was not perfect and that when strong traction was made upon the uterus the patient complained of abdominal discomfort.

TECHNIQUE.

The details of the technique followed are given in the *Semaine Médicale* of May 16th, 1900, and later Tuffier is careful to disclaim any originality save in some practical technical points of his procedure. An ordinary hypodermic syringe will suffice, provided its construction admits of absolute sterilisation. The best, therefore, is the glass syringe made by Luer, which can be boiled without injury and which never gets out of order. The needle should be strong, of platinum, about nine centimetres in length—i.e., three and a half inches—with its penetrating sharpened portion cut very short. The solution of cocaine used is 2 per cent. and must be freshly prepared and sterilised. It seems, however, probable that in the long run weaker solutions will become of more frequent use and that the solution of cocaine used will vary from 1 in 100 to as little as 1 in 400. The patient should be seated, bent forward slightly, with both arms in front of him (see figure). The lumbar region is thoroughly cleansed and the anatomical landmarks are noted. It will be found that a horizontal line between the two highest points posteriorly of the iliac crests passes immediately below the fourth lumbar spinous process. Above or below this line in the intervertebral space the needle will freely enter the medullary canal. The left index then marks the fourth spinous process and the patient is told to bend well over forwards, thus increasing the space between the vertebræ by nearly three-fifths of an inch. The needle alone is then entered at about a centimetre (two-fifths of an inch) to the right of the middle line in a direction forwards and inwards in the third or fourth lumbar interspace, as may be selected. The third lumbar interspace is that commonly chosen, but the fourth may be punctured with equal facility and effect and Legueu frequently injected the cocaine into the second lumbar space. It is interesting to recollect that Corning's first injection was made between the twelfth dorsal and the first lumbar vertebra. The needle thus pierces the skin, the subcutaneous tissue, the lumbar fascia, the sacro-lumbar muscles, and the quadratus lumborum and enters the spinal canal through the ligamentum flavum which alone offers any noticeable resistance.



Cocainisation of the spinal canal.

As the needle enters the subarachnoid space the absence of resistance is at once felt, and almost at once the clear, yellowish, cerebro-spinal liquid escapes, drop by drop. The syringe has been already prepared, containing from one to two cubic centimetres of the 2 per cent. solution—i.e., from one to two centigrammes of cocaine (from 20 to 30 minims, containing about a quarter of a grain of cocaine)—and is now fitted to the needle and the solution is very slowly injected. The quantity of cocaine injected, it will thus be seen, is very small, and yet the anæsthesia resulting will last about one and a half hours. The little puncture is then sealed with collodion, the patient lies down, and an assistant at once begins to cleanse and to prepare the field of operation. The analgesia passes gradually from the feet upwards,

and for a laparotomy it may be necessary to wait from ten minutes to a quarter of an hour before commencing.

Tuffier, whose experience is probably greatest of living surgeons, has not yet observed an accident which he could attribute to the injection or to the cocaine. He has by this method performed over 200 operations of which more than half have been intra-peritoneal. Legueu[7] prefers eucaine to cocaine owing to its lesser toxicity and its greater stability during sterilisation by heat. Hydrochlorate of eucaine may be sterilised either in an autoclave or by heating the solution for half an hour on three successive days to 100° C. Hydrochlorate of cocaine, on the other hand, at this temperature will decompose into methylic alcohol, benzoic acid, and ecgonine, and can only be raised to a temperature of 80° C. Legueu's conclusion after some weeks' experience and over 50 operations is that as a method of anæsthesia it is destined to take an important place in a great number of operations, and he specifies all below the level of the umbilicus, all operations on the perineum, the lower urinary passages, the lower limbs, always supposing that muscular contractions do not too greatly embarrass the surgeon. Thus, in one case of fracture of both bones of the leg with great displacement, while Legueu was able freely to manipulate and attempt to reduce the fracture without any pain the muscular contraction persisted and a few days later the bones required to be stitched under chloroform.

Both Legueu and Tuffier maintain that throughout they have met with no serious results either during or after an operation and both enter into minute detail as to the sensations experienced by the patients. These almost at once mention itchings and tingling sensations of the legs, due possibly to some irritation of a nerve of the cauda equina. Some also refer to a passing sense of suffocation, with perspiration and pallor, all, however, of brief duration. The more important and constant symptoms are vomiting, headache, and rise of temperature.

Vomiting in two-thirds of the cases is absent and the patients seem almost unaware of what is being done. Reclus has recommended that before even an endermic injection of cocaine the patient should take food. The vomiting is not according to the quantity of cocaine injected but more probably depends upon some individual susceptibility, as indeed is the case with chloroform and other general anæsthetics.

Headache occurs in rather more than half the cases, but is, as a rule, slight and of short duration. It usually comes on a few hours after the operation, to disappear in the 24 hours, and not uncommonly causes sleeplessness.

Elevation of temperature occurs in about 20 per cent. and has been observed in such comparatively simple cases as anal fistula, varicocele radical cure of inguinal hernia, varying from 102° to 104° F. It invariably had fallen to normal the following day in Legueu's cases. The pupils are occasionally dilated, both retention and incontinence of urine have been remarked, and the sphincter ani may relax shortly after the injection.

At the Thirteenth International Congress of Medicine held in Paris in August, 1900, more serious objections were made. Dr. Severeannu of Bucharest had observed a general depression lasting a day or two which had caused him considerable anxiety, and he considered it a serious inconvenience to the surgeon that the patient should be consciously present at his own operation. Dr. Racoviceanu,[8] also of Bucharest, reported three cases in which he had injected four centigrammes, or three-fifths of a grain, and had been obliged to have recourse to artificial respiration for 20 minutes and hypodermic injections of ether, and added that "he had knowledge of two deaths in Roumania following lumbar injection of cocaine." This statement, however, is altogether lacking in precision and receives no confirmation from other surgeons.

It is strange, too, that Racoviceanu concludes his *mémoire* by stating that while the accidents he has observed prevent him from recommending the method to others, he is personally very satisfied with the results he has obtained. Bier, the originator, is himself doubtful of its practicability and in February, 1900, wrote to Cadol[9] that he thought the method, owing to the subjective disturbances sometimes caused by the cocainisation of the spinal cord, was not yet practical. Delbet[10] concludes that it offers no advantages over chloroform, but, on the contrary, has the same contra-indications with the further disadvantage that the anæsthesia is not complete.

The number of published observations now amounts to nearly a thousand.

MANCHESTER.

(FROM OUR OWN CORRESPONDENT.)

"Irish" Butter.

AN appeal case was concluded at the Preston Quarter Sessions on Jan. 5th in which the decision, according to one of the reports, "is of supreme importance to provision merchants, farmers, and dairymen throughout the British Isles," but the British public are passed over, though one would have thought that their interest in the question deserved mention. It all turned on the oft-debated point of the percentage of water in the butter. A company with the quaint title of "The Peace and Safety Industrial Society, Limited," of Rawtenstall, had been convicted by the Rossendale magistrates of having sold a pound of butter "not of the nature, substance, and quality demanded by the purchaser," as it contained 19·30 per cent. of water, contrary to Section 6 of the Food and Drugs Act, 1875. Two methods of making butter are used in Ireland, in one of which it is treated with a strong solution of salt, which is called "brining." By this method it is very difficult to bring the quantity of water left in the butter below 20 per cent., so that if pickling, or "brining," be a "right and necessary process," the 19·30 per cent. present in this case was "unavoidably mixed in the process of preparation." It seems that all "Irish" butter, as popularly understood, is made in this way, while Kiel, or "Irish creamery" butter, is made with dry salt. The former is made to keep for some time, while the latter, less salted, is used as fresh butter. The case was an attempt to question the system of "pickling" as against "dry-salting," with a view to bring about a uniform standard of 15 or 16 per cent. or thereabouts of water as an outside limit in all butter exported from Ireland. "Irish" butter comes into England in enormous amount, of which Lancashire takes a large proportion, and it is said that a standard lower than 20 per cent. would imperil this trade. One solution is that there should be two standards, one for each class of butter. The question of fraud scarcely enters, for "Irish" is known to be lower in quality than Kiel or "Irish creamery" and sells at a lower price. It is very largely used by the working classes in Lancashire and would probably be preferred to the less heavily salted Kiel or creamery butter. The decision of the magistrates was that the conviction should be quashed and their opinion was unanimous "that the question of fixing a presumptive standard or standards merits the early attention of the Board of Agriculture."

Proposed Jewish Hospital.

The conference on the proposed Jewish hospital for Manchester was resumed yesterday under the presidency of Councillor C. Dreyfus. Two gentlemen (the Rev. Dr. Salomon and Mr. N. Laski) said that owing to the holidays no reply had been received from the hospital authorities, but the Rev. Dr. Salomon was almost sure that it would be a favourable one. He wished to bear testimony to the kind treatment the Jewish patients received "at the hands of the doctors and nurses." It was thought by some that the committee was not representative, and it was agreed to invite repreenatives of the Jewish congregations and charitable committees in the city to discuss "the various suggestions for attaining the desired end." The chairman thought that repeated adjournments did no good, but he hoped that in a fortnight or three weeks they would arrive at some definite conclusion. The feeling on the whole seems rather in favour of a Jewish hospital than to make use of those hospitals now existing.

Milk and Enteric Fever.

At the meeting of the Salford Council on Jan. 2nd it was stated in a report from Mr. C. H. Tattersall that there had

been 19 persons suffering from enteric fever within a fortnight in the Regent-road district, all of whom had been consuming milk supplied by one dealer. The farms from which the milk had come were visited by the medical officer and the veterinary inspector and found free from disease; but the milkman had been ill, and though his illness was said to be pneumonia it was extremely suspicious, and in Mr. Tattersall's opinion this was the source of infection. Instructions had been given to "close the milkhouse unless the dealer consented to be removed into the country within 24 hours so that his premises might be thoroughly disinfected, and also that various sanitary alterations be made to the back premises." These precautions were no doubt good as regards Salford, but if the man were still a source of infection he would be an undesirable guest in "the country," and it would have been better that he should have been sent to a hospital where isolation could have been practised. If, on the other hand, he had ceased to be a source of infection, although the disinfection of the premises was right it does not seem that his removal was required.

"Friendly Society Notes."

In an article on friendly societies from "A Special Correspondent," which appeared in the *Manchester Courier* of Jan. 3rd, "the difficulties between the medical profession and the friendly societies" are said to "seem as far off a settlement as ever." It is interesting to see how the question strikes a lay person, evidently an admirer of the societies. He says that representatives on the "board of conciliation" were long ago appointed, "but the medical profession, which at first responded so readily, has shown a curious dislike to accepting any practical scheme of considering disputes and removing difficulties," which the writer thinks unfortunate for the profession, "as it cannot break down the system of combination, even if it were desirable to do so," and that it would be better to accept the inevitable. He says the profession recognise that combination secures, by small weekly payments for medical attendance, large sums "which otherwise would be spent in an entirely different manner." Does this mean that if medical attendance were not paid for in this way it would not be paid for at all? He then goes on to say that the profession, "recognising this, and being ready to profit by it, ... at the same time wish to pick and choose and say which of those who have paid shall receive the benefit." This apparently refers to the question of wage limit or to there being some arrangement to prevent the rich man paying his paltry pence into the treasury and insisting that he shall receive the medical benefits intended for those who cannot pay the modest charges of the general practitioner. Some such arrangement for preventing an abuse of the system seems only equitable, but this "Special Correspondent" says that "so long as this attitude continues to be adopted by the medical profession so long will the difficulty continue. There may be abuses in connexion with the existing system, but they are trifles light as air when put in the scale against the advantages—advantages shared alike by the medical profession and the general community." A fine passage no doubt from the journalistic standpoint, but the writer will not find many medical practitioners enthusiastic about the advantage of attending the well-to-do shopkeeper or employer of labour for less in many cases than a penny a week as his individual payment.

Long Service.

On Dec. 20th, 1900, at the meeting of the Northwich Board of Guardians a letter was read from Mr. Thomas Moreton stating that after 41 years' service as district medical officer, vaccination officer, and medical officer to the workhouse he was, owing to ill-health, obliged to resign these offices. The resignation was accepted with regret and a resolution was passed thanking Mr. Moreton for his services in the interests of the public.

Manchester Volunteer Medical Staff Corps: Further Increase of Establishment.

Information was received at headquarters on Jan. 7th that three additional transport companies were to be formed in connexion with this corps. This will necessitate the enrolment of three officers and 120 non-commissioned officers and men in addition to the two transport companies already formed. A special staff sergeant instructor from the Army Service Corps has been attached to the corps by the War Office to carry out all the necessary instruction required. The object of these companies is to provide for the driving of the ambulance wagons and service wagons which are part of the equipment of a bearer company and for the proper care of horses, wagons, harness, &c., which are used in the conveyance of wounded and sick soldiers. The training is full of interest and each member who joins goes through a complete course of riding, driving, and stable management. Many young men in Manchester and neighbourhood will no doubt avail themselves of this opportunity of learning everything connected with horses, and probably numbers of candidates will apply during the next few days at the headquarters of the corps at 336, Chester-road, Manchester, to obtain particulars.

Drink Tragedy.

An inquest was held on Jan. 7th by the city coroner concerning the death of a middle-aged woman who died on Jan. 4th in the Ancoats Hospital from the effects of severe burns. The report speaks of it as disclosing "a story of singular pathos," of the apparently ungovernable craving of the woman for drink, and of her employing her boy, 10 years of age, to fetch it for her. According to his narrative he was sent soon after daybreak on Dec. 3rd to pledge his father's Sunday clothes, for which he received 9*s*. His mother sent him seven or eight times for whisky, all of which she drank herself. It was her frequent practice to send him to pawn clothes and to fetch whisky with the proceeds. "He usually went for whisky on Saturdays and Mondays." After drinking the whisky she fell asleep before the fire and he went out to "play." An elder brother found her lying unconscious with her clothes in flames. She was taken to the hospital where she died. The publican denied that he served the boy, but the coroner believed the latter after carefully investigating the conflicting statements. This tragedy might have been averted if there were safe custody for habitual drunkards and if the selling of drink to young children were made penal. Nothing is said in the report about the husband, but what a picture the story gives of a wretched family life ruined by drink.

Arsenic in Beer.

Legal proceedings have been commenced in connexion with some of the cases of arsenical poisoning by beer.

Jan. 8th.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Edinburgh Royal Infirmary.

THE annual general meeting of the contributors to the Royal Infirmary of Edinburgh was held in the Council Chambers, Edinburgh, on Jan. 7th, Lord Provost Steel being in the chair. Mr. W. S. Caw, the clerk and treasurer, submitted the manager's annual report for the year ending Oct. 1st, 1900. The total number of patients treated in the hospital during the year had been 9569, as against 9694 in the previous year. The average daily number of patients was 701, as against 711, and the average daily number of children was 58. The average time each patient was under treatment was 26·7 days, this being exactly the average of the previous year. Of cases admitted Edinburgh sent in 4668, Leith 513, and the country 3733. There had been 768 deaths, and of these 218 took place within 48 hours after the patients' admission. In the medical and surgical out-patient departments 32,455 cases were treated, being an increase of 3016 on the previous year. The ordinary income amounted to £30,009 0*s*. 5*d*., as compared with £30,739 10*s*. 7*d*. for the preceding year. The ordinary expenditure amounted to £47,868 5*s*. 6*d*., being £3986 1*s*. 7*d*. more than in the previous year. The entire ordinary expenditure during the year (including the cost of out-patient departments) per average occupied bed was £68 5*s*. 8½*d*., or £6 11*s*. 4*d*. more than in the previous year. The legacies and donations of £100 and upwards received during the year amounted to £69,314 12*s*. 8*d*. In this total was included the munificent donation by Mr. Thomas Aitken of Nivingston of £40,000, in commemoration of which the managers had named a ward. The capital expenditure amounted to £21,038 15*s*. 10*d*. in all, the principal items being £14 599 17*s*. 11*d*. from the extension fund for the new pavilions, and £4260 8*s*. 1*d*. from the general fund for reconstruction of kitchen and stores. In addition to the "Aitken" ward two wards in the new Gynæcological Pavilion were named the "Yule" and

the "Waddell" wards respectively, to commemorate the names of Mr. J. L. B. Yule and Mr. Peter Waddell, who both left large bequests to the institution. At the beginning of the year the nursing staff numbered 184, and at the close of the year 195. The average for the year was 192. There had been 670 applications for admission, against 578 in the previous year. It was interesting to note that the matrons of 39 Scottish institutions had received their training in Edinburgh Royal Infirmary. The draining and plumbing of the older part of the infirmary were being completely renewed according to a scheme elaborated by the burgh engineer. The total number of patients admitted to the convalescent home at Corstorphine during the year had been 1321. The daily average was 70·1. The managers regretted to report that the income of the convalescent home failed to meet the expenditure by the considerable sum of £1225 4*s.* 8*d.* The adoption of the report was formally moved by the Lord Provost and seconded by Mr. Patrick Blair, W.S. The following were elected managers to represent the contributors for the ensuing year: Dr. Claud Muirhead, Sir Andrew Macdonald, Mr. Patrick Blair, W.S., Colonel M'Hardy, C.B., Miss E. S. Haldane, and Miss Agnes C. Imlach. The meeting was adjourned for a fortnight to receive the report of the committee of contributors.

The Western Infirmary, Glasgow.

There are some indications that the Western Infirmary, Glasgow, will ere long be extending its borders. At a recent meeting of contributors it was announced that nearly 300 patients were waiting for admission, a state of matters which must necessarily lead the directors to contemplate a considerable increase in the number of beds. The directors are at present engaged in raising funds for the rebuilding of the out-patient department. These proposals, together with the schemes for providing increased laboratory accommodation at the university and for the building and equipment of a new technical college, offer abundant opportunities for the liberality and patriotism of the inhabitants of Glasgow and the west of Scotland.

New Salmon Hatchery for the Tweed and Teviot.

In consequence of a movement which was started two years ago a salmon hatchery for the river Tweed has just been erected. The hatchery, which is fitted with all the modern improvements, is situated at East Learmouth, about a mile from Cornhill-on-Tweed, on an excellent site which has been granted by Earl Grey. The management of the hatchery is under the supervision of Mr. F. J. Douglas, Springwood Park, Kelso, and Mr. George Grey of Millfield. The hatchery is a private undertaking with which the River Tweed Commissioners have no official connexion, and the cost of which has been subscribed to by every river proprietor from Torwoodlee to Tillmouth. The building is 48 feet long by 20 feet wide and seven feet high inside. It is fitted with 12 boxes capable of holding in all 18 grilles, so that the 12 boxes combined have a capacity for about 300,000 salmon ova. If the fry were hatched three times in a season the output would not fall far short of 1,000,000 salmon fry. The water-supply is carefully filtered before passing to the boxes. There is in the hatchery an impounding tank of 1100 gallons capacity for keeping the salmon in after capture until they are ready for spawning. The young fry will be kept until they are six months old. For this purpose six ponds are to be constructed 40 feet long by eight feet wide by four feet deep. There are those who think that fish-culture may play an important part from a medical point of view in the future.

Jan. 8th.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

The Public Health of Dublin.

AT a meeting of the Dublin Sanitary Association held on Dec. 14th, 1900, the council noted that in the week ending Dec. 8th, only 17 cases of scarlet fever were notified in the borough of Dublin and the urban districts of Rathmines and Pembroke, while the admissions of scarlet fever cases to hospital were 17. This would imply that several cases escaped notification, as it is not likely that all the patients were sent to hospital. The corresponding figures in reference to measles, typhoid and typhus fevers, with diphtheria, seemed to point to the same conclusion. The council met again on Jan. 3rd, and, having received in the meanwhile many returns, observed that a wide diversity as to the diseases which are notifiable existed in the several districts which have adopted the Act. Thus Pembroke requires whooping-cough and measles to be notified, while Rathmines and Bray require neither of those, but Rathmines specifies dysentery. Such variations in the list of notifiable diseases seriously cripple the working of the Act. The Corporation of Dublin must soon consider the report of the Commission which sat in Dublin a year ago and advised—"That the duties of medical officer of health should no longer be discharged by the present 16 dispensary medical officers of health, but that in future those duties should be discharged by an assistant medical officer of health who should receive an adequate salary and who should give his whole time to the duties of his office." In the meanwhile, at a meeting of the municipal council held on Jan. 7th the chairman of the Public Health Committee moved the adoption of the report from that committee *in re* recommendations of the committee appointed by the Local Government Board of Ireland to inquire into the public health of the city of Dublin. The report, which was unanimously adopted by the committee, contained many recommendations in reference to the scheme for housing a large number of the labouring and poorer class, the regulation of tenement houses, the inspection of dairy yards, arrangements as to hospitals, &c. It was formally brought forward by the Lord Mayor and passed unanimously. A long discussion took place subsequently as to the adoption of Podewell's apparatus for the destruction of diseased meat so strongly recommended by the delegates recently sent out by the corporations of Dublin and Belfast to inquire into the system adopted in the larger continental towns. An amendment postponing the report for six months was carried. The council then addressed itself to the question whether tuberculosis should be included in the list of notifiable diseases. The Lord Mayor was strongly in favour of the proposal and remarked that although the notification of tuberculosis was not compulsory in England no city in England showed a record of 1000 deaths every year from that disease. Ultimately a suggestion to postpone the matter in order to acquire further information was adopted.

The Rainfall in Belfast.

The total rainfall for the year 1900 in Belfast was 40·07 inches, being 0·71 inch in excess of that of the previous year. In December there were only eight days on which rain did not fall and from the 23rd until the end of the month there was not a dry day, and on one day (Dec. 26th) 1·03 inches fell. The total amount of rainfall for December was 5·26 inches. These facts indicate that Belfast is one of the wettest places in the kingdom.

The Royal Victoria Hospital, Belfast.

A gentleman in Holywood, near Belfast, in gratitude for services received some years ago by his son when a patient in the Belfast Royal Hospital, has given property to the endowment fund of the Royal Victoria Hospital which will secure an annual rental for ever of upwards of £50. This is one of the largest gifts which the charity has yet received.

Death of James Ross Thomson, L.R.C.P. Edin., C.M. Glasg.

I regret to announce the death, at the advanced age of 84 years, of Mr. J. R. Thomson, which took place at his residence, Church-street, Ballymoney, on Jan. 7th. He had practised almost all his life in Ballymoney, where he was medical attendant to the union workhouse. He was buried on Jan. 9th. Enjoying a large *clientèle*, Mr. Thomson was greatly liked both by rich and poor. He was compelled by advancing years to retire a few years ago from his workhouse duties, in which he was succeeded by his nephew.

Scarlet Fever in Portadown.

An epidemic of scarlet fever is prevailing in the urban district of Portadown. Mr. J. L. Rowlett, medical officer of health, advised the Portadown District Council that a suitable disinfecting chamber should be provided to sterilise the clothing, and that all persons suffering from the disease should be isolated in an infectious hospital; but to this course both the parents and apparently (from the discussion at their meeting on Jan. 4th) some of the Portadown councillors object.

Jan. 8th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

The Sanatorium of Angicourt.

IN my last letter I mentioned that this sanatorium after having taken 14 years to build was just about to be opened. The cost has been enormous owing to the old-fashioned notions of the architects, for instead of building lightly constructed edifices of brick and iron in isolated blocks after the methods approved of by modern hygienic science, they have constructed a veritable barrack in stone which will only hold a small number of patients, which has taken an interminable time to build, and which represents many persons dead from tuberculosis who succumbed while they were waiting for the finishing of the building where they hoped to be treated. Although the sanatorium has at present no patients, yet for the last two years it has rejoiced in the possession of a director and this official has recently sent an appeal to the Hospitals Medical Society praying its members to formulate the conditions of admission to the sanatorium and whether its benefits are to be reserved for quiescent cases of tuberculosis or whether acute cases are to be admitted. A committee of the society, composed of M. Faisans, M. Merklen, M. Mosny, M. Rendu, and M. Siredy, have reported on the matter and without entering into the question of acute or quiescent cases have drawn up the following rules. 1. The Angicourt sanatorium shall be open to indigent inhabitants of Paris afflicted with pulmonary tuberculosis, but whose lesions are presumably curable. 2. No patient shall be admitted to the sanatorium without his furnishing a sanitary record (*dossier*) drawn up by his medical attendant showing clearly his family and personal history, a history of his tuberculosis, and a complete daily clinical record extending over at least eight consecutive days setting out details of his pulmonary lesions, his rectal temperatures, his pulse, his respiratory condition, an analysis of his urine, his weight, and the results of a microscopical examination of his sputa, including the results of a search for bacilli carried out in more than one method. 3. All these *dossiers* shall be examined periodically by a medical committee appointed for that end by the Hospitals Medical Society. The committee further say that records corresponding to the sanitary *dossiers*, which shall be drawn up during the stay of the patient in the sanatorium will allow of the medical director forming an opinion of the efficacy of the curative properties of the sanatorium treatment and consequently of the advisability or the reverse of keeping up the sanatorium. This report of the committee was carried by the society unanimously. It is evident that if the authorities succeed in getting drawn up both the sanitary *dossiers* and the records illustrative of the patient's condition while in hospital there will be a grand opportunity for making an experimental study of the results of treatment, but it is much to be feared that in the case of many of the patients who will belong to just that very poor class who do not consult a medical man with regularity, it will be impossible to obtain sufficiently accurate details of their condition, for they will not have been under observation for a sufficiently long time. The Hospitals Medical Society should have gone a step further and arranged for a sort of permanent consulting institute at which patients might apply with regularity and so have their *dossiers* accurately drawn up.

The Alcohol Question in Parliament.

The Chamber of Deputies and the Senate have just completed the draft of a Bill which has been for a long time in preparation with regard to the trade in alcoholic drinks. The debates on the matter were interminable and showed in a cruel light the pretensions of the trade, who did not hesitate to poison a whole country and to destroy their fellow-creatures if only they could be assured of a sale for their goods. Under such conditions the crusade against alcohol which certain philanthropists started and which was warmly supported by the medical profession presented almost insuperable difficulties. How try to diminish the consumption of alcoholic drinks in France when a great part of the population gets its livelihood by making the same and elects those members who form a majority of the Chamber? How restrict the number of drink-shops when it is by these that the deputies are practically elected? How hope to restrain the sale of alcohol by fiscal laws when even the new law respects the *privilège des bouilleurs de cru*—i.e., the right of distilling alcohol without further taxation—which every proprietor who makes wine or cider from his own vineyard or orchard possesses? The fraud to which this right gives rise is most extensive and it is calculated that the revenue loses 400,000,000 francs per annum owing to the frauds which this right brings in its train. It is quite common to see large landowners distil alcohol not only from the produce of their own lands but also from wine or cider surreptitiously brought in. Besides, the inspectors whose duty it is to prevent these frauds are generally powerless owing to the amount of electoral corruption which exists. A too zealous agent runs the risk of being recalled by the deputy for his district whose election is generally in the pocket of the large landowner. Medical men and hygienists have at least done their part as regards the thousand-and-one varieties of alcoholic drinks sold under the name of "amers" and "apéritifs" which play such a large part in the alcoholic intoxication of France. Many have demanded that these preparations should be ruinously taxed, but the deputies, with the fear of the drinkshop before their eyes, have not dared to accept the proposals. A Socialist deputy, however, M. Vaillant, had the ingenious idea of asking that the sale of those alcoholic drinks which the Academy of Medicine had definitely pronounced to be harmful to the public health should be interdicted, a demand which the deputies dared not refuse, and hence will start a far-reaching reform if the Minister concerned has only the courage to carry out the provisions of the Bill. M. Vaillant persisted in his campaign, for when the Bill after having passed the Senate came down to the Chamber of Deputies a second time for amendment M. Vaillant complained that the Minister in charge of the Bill had not been sufficiently categorical; and he succeeded in getting the Chamber to pass a resolution that the Government from henceforth should get the Academy of Medicine to declare that *liqueurs apéritifs* and other alcoholic drinks containing essences were dangerous to the public health, so that their manufacture, circulation, and sale should be put a stop to.

Deaths of Medical Men in Paris.

Last week there occurred the deaths of several well-known medical men. Dr. Béranger-Féraud, formerly *médecin en chef* to the navy and President of the Conseil Superieur de la Marine. He left a number of valuable works on the subjects of the pathology of tropical diseases and on pathology from the standpoint of a naval surgeon.—The death is also announced of Dr. de Beauvais, one of the oldest of the Paris practitioners, who died at the age of 79 years. He left a valuable collection of clinical notes on cases and on practical therapeutics and the reputation of a high-minded and courageous man. He was formerly President of the Medical Society of Paris and chief surgeon to the prisons. In 1848, when *interne* at the ambulance station of St. Lazare, he nearly died from the effects of septicæmia contracted during the performance of an operation. He worked magnificently through the cholera epidemic of 1849 and was at the early age of 28 years made a Chevalier of the Legion of Honour as a reward for his conduct. In 1871, while serving as chief medical officer at Mazas, he was very nearly being shot by the Communists for being too kind to the unfortunate hostages.—The deaths are also announced of Dr. Duclos of Tours, professor of clinical medicine at the medical school of that city; of Professor Dubreuil, professor in the Faculty of Medicine of Montpellier and formerly *professeur agrégé* in the Paris Faculty of Medicine; and last, and most distinguished of all, of Professor Potain.

Jan. 8th.

ROME.

(FROM OUR OWN CORRESPONDENT.)

Professor Grassi and the Mosquito-Malaria Theory.

PROFESSOR GRASSI contributes some "Historical Notes on the Recent Discoveries regarding the Transmission of Malaria" to the *Policlinico* of Dec. 29th which are evidently intended as a reply to Major R. Ross's recent letter to that journal on the question of priority in the mosquito-malaria theory.[1] After enumerating the results obtained by Major Ross in his experiments with human malaria in 1896–97–98 and stigmatising them as either erroneous, inconclusive, dubious, or positively misleading, he passes to Major Ross's discovery—which he claims to have himself made with Feletti in 1890—

[1] THE LANCET, Dec. 8th, 1900, p. 1684.

of the evolution of proteosoma in the body of the gray mosquito. For this beautiful demonstration, so much admired by other authors, Professor Grassi has no word of praise, only remarking that from a zoological point of view the figures and description given by Major Ross are quite incomprehensible. He also refuses to admit that it has more than a doubtful value as a guide to what happens in human malaria, since parasites very similar to one another may have totally different life-cycles. As examples, he cites the filaria medinensis which, unlike other filariæ, does not propagate itself through the mosquito; the parasite of bovine malaria which is conveyed through the larvæ of the tick to its new host; and one of the two parasites of bird malaria which it has not been found possible to cultivate in the mosquito. Professor Grassi quotes from a note by Major Ross in the *Annales de l'Institut Pasteur*, dated Dec 31st, 1898, with the purpose of showing that Major Ross himself did not at that time regard his discovery as settling the question, but on the contrary, considered that much remained to be done before a solution could be arrived at. He next proceeds to enumerate the questions in regard to malaria which, in his view, Major Ross's experiments left unsolved: (1) whether the theory of the propagation of malaria by means of mosquitoes was borne out by facts; (2) which species of the many included under the name "mosquito" was capable of propagating human malaria; (3) whether the parasites of human malaria had a life-cycle corresponding to that of the parasite of bird malaria; (4) whether, as appeared probable, man was only an accidental host of the malarial parasite which reproduced itself indefinitely in the mosquito; (5) whether man became infected only through the bites of mosquitoes; (6) whether the new experimental data explained the empirical knowledge which we possess regarding human malaria; (7) whether other mammals acted as the hosts of the parasite of human malaria; and, lastly (8), how the facts discovered by Major Ross ought to be interpreted zoologically so as to reconcile them with those already known about other protozoa. Reverting to his own work and to that done in collaboration with Bignami and Bastianelli, Professor Grassi claims to have settled many of these questions, asserting that he was the first to proclaim the intimate relationship between the presence of the anopheles claviger and the occurrence of malaria; that to him, along with Bignami, is due the credit of experimentally inoculating the human subject with malaria by means of mosquito bites; and that to him also belongs the merit of having demonstrated by exhaustive observations and experiments, conducted with the help of Bignami and Bastianelli, the entire life-history of the human malarial parasite. He adds to these many other points which he claims to have elucidated in regard to the natural history of the parasite and the etiology of the disease, and he concludes by reiterating an assertion that our knowledge of the mode of transmission of human malaria, which he now regards as complete, at any rate for Italy, is the result of researches begun by himself, continued with the assistance of Bignami and Bastianelli, and completed by himself alone.

Legislation for the Supply of Quinine.

In the light of recent discoveries it has become evident that one of the most efficient measures for the prevention of malaria must lie in the cure of existing cases of the disease, since it is chiefly, if not entirely, from these that fresh individuals are infected by the mosquito. Unfortunately, the difficulty of procuring that sovereign remedy in malaria, quinine, has hitherto proved a great obstacle in the way of carrying out this important method of prophylaxis in many of the malarious districts of Italy, where there are often no drug stores, or where, if such exist, the quinine is often very impure, or is so high priced as to be beyond the reach of the poor labourers who most of all require it. Frequent attempts to provide against this difficulty by creating a Government monopoly have been made by Parliament from time to time, but hitherto without success, owing to the determined opposition of those interested in the sale of quinine. Now that science has been able to show the cure of malaria to be a prophylactic measure of the highest public importance every obstacle has been overcome, and a Bill has been framed which it is hoped will fully meet the necessities of the case. By this law it will become the duty of the Government to provide for the sale of quinine of the best quality at a very moderate price throughout the whole country. Where pharmacies or dispensaries are already established the sale will be confided to these, but where such do not exist it will be entrusted to the salt and tobacco shops (which are Government monopolies), or failing these to any suitable person available. The Superior Sanitary Council will determine the form and must approve the quality of the quinine, which it is proposed to supply in three-grain tabloids put up in hermetically sealed tubes, each tube to contain 10 tabloids. The preparations recommended are the hydrochlorate, the sulphate, and the bisulphate. The price of the hydrochlorate to the public must not exceed 40 centesimi (4*d*.) per tube, and that of the sulphate and bisulphate 32 centesimi per tube. No other salts of quinine must be sold except by a chemist, and the prices of these must be so regulated as to correspond with the tariff laid down under this law. Although the price thus fixed is low, it leaves a margin for profit, and the law provides that the resulting fund shall be applied to the purpose of combating the causes of malaria. A mixed commission of unpaid members selected from both Houses of Parliament and from the different governmental departments interested will administer this fund to the best advantage. The Bill embodying these provisions passed the Chamber of Deputies on Dec. 11th, 1900, and has already gone to the Senate, which it is hoped will approve of the measure as it stands.

Jan. 4th.

CONSTANTINOPLE.

(FROM OUR OWN CORRESPONDENT.)

The International Sanitary Board.

IN my last letter I gave your readers some details of the difficulties which have arisen in connexion with the International Sanitary Board owing to the death of Dr. Vitalis, the inspector adjoint. There are at present three persons who have been appointed to fill this post—namely, Dr. Duca Bey, who has been appointed by the Superior Sanitary Council; a former custom-house official who is not a medical man, and who has been appointed by the Turkish Government without salary; and thirdly, Dr. Eiterer, also appointed by the Turkish Government, to whom a salary will be paid by the Ministry of Finance. The appointment, whoever gets the post, will have to be confirmed by the Sultan. Owing to the Turkish Government having infringed the rights of the Sanitary Council by appointing one who is not a medical man, the Ambassadors have withdrawn their delegates to the Council. The conflict is particularly unfortunate at the present time owing to the outbreak of an epidemic at Smyrna, details of which follow.

Alleged Plague in Smyrna.

A very fatal disease, the nature of which is not definitely ascertained, has appeared in the village of Thomaso, near Cordelio, in the vicinity of Smyrna. The first patient was a man who suddenly fell ill in Smyrna during the first week of December, went home to his relatives in Thomaso, and died eight days after the beginning of the illness. Other cases soon occurred in the village and by Jan. 2nd there had been in three families 12 attacks with 11 deaths, the patient from Smyrna not included. In most instances the diagnosis was pneumonia. A long report on the circumstances has been sent to Constantinople by Dr. E. F. Mizzi, *médecin sanitaire* of Smyrna, pointing out that there have been no symptoms of implication of the lymphatic system, so that in the absence of bacteriological examination there was nothing to suggest plague, and arguing that the disease was probably infectious pneumonia due to "*grippe maligne*." A bacteriologist from Constantinople arrived in Smyrna on Jan. 2nd, but no examinations of the above-mentioned cases could be made, as all the deceased had been buried. On Jan. 3rd, however, a man who had been attacked with illness in Smyrna was found to have an axillary bubo and the plague bacillus was discovered on direct microscopic examination.

Poisoning Mischance at a School.

During the evening classes held at one of the schools at Beylerbey all the pupils were poisoned by the fumes from a charcoal brazier which had been lighted to heat the classroom. None of the cases, however, was attended with fatal results.

Assassination of a Medical Man.

A few weeks ago Dr. Saltellario, a well-known physician at Gumendjeh, near Salonica, was called out to see a patient, and on his way he was shot from behind, the bullet entering under his shoulder and passing through the

chest to the opposite lung. He was taken back to his house, where he is being attended by Salonica physicians. The assassins have been arrested, among them, I am sorry to say, a Dr. Tartchieff, a Bulgarian physician who is an affiliated member of the Bulgaro-Macedonian Society. Similar outrages have occurred in Bitolia, but there the assassins were not arrested.

Jan. 4th.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At the primary examination held recently the following candidates passed in the subjects indicated:—

PART I.

Biology.—C. H. Colley, Royal Free Hospital; and J. G. Lewis, Cardiff.

Chemistry.—E. C. Curtis, Aberdeen; F. G. Dobson, Leeds; F. W. March, Durham; W. B. Skelton, Guy's Hospital; and P. B. Whitington, London Hospital.

Materia Medica and Pharmacy.—R. S. Dollard, Royal College of Surgeons, Ireland; K. Knowles and K. A. Platt, Royal Free Hospital; W. B. Skelton, Guy's Hospital; M. C. Vivian, Royal Free Hospital; and C. Watson, Westminster Hospital.

PART II.

Anatomy.—J. Bromley, Guy's Hospital; J. Jones, Manchester; K. Knowles, Royal Free Hospital; D. J. Lewis, London Hospital; C. G. Martin, St. Bartholomew's Hospital; H. G. Peel, Leeds; K. A. Platt, Royal Free Hospital; G. H. Rains, Bristol and Westminster Hospital; A. Rogers, Cardiff; C. C. Rushton, Manchester and University College Hospital; D. A. Stepney, Royal Free Hospital; M. B. Taylor, Guy's Hospital; J. M. Wall and A. L. Walters, St. Thomas's Hospital; and J. S. Ward, Sheffield.

Physiology.—J. Bromley, Guy's Hospital; J. Jones, Manchester; K. Knowles, Royal Free Hospital; D. J. Lewis, London Hospital; E. H. McMahon, Charing-cross Hospital; C. G. Martin, St. Bartholomew's Hospital; S. Northwood, Birmingham; C. H. Osmond, Glasgow; H. G. Peel and W. V. Pegler, Leeds; A. Rogers, Cardiff; C. C. Rushton, Manchester and University College Hospital; M. B. Taylor, Guy's Hospitals; A. L. Walters, St. Thomas's Hospital; J. S. Ward, Sheffield; and S. H. R. Welch, Charing-cross Hospital.

UNIVERSITY OF OXFORD.—In a congregation holden on Dec. 17th, being the last day of Michaelmas Term, the following degrees were conferred:—

M.B.—Edmund H. Hunt, Balliol; Herbert S. French, James E. H. Sawyer, and William V. Shaw, Christ Church; Lawrence H. C. Birkbeck, Trinity; Vincent S. Hodson, Marcon's Hall.

CORONERS' INQUIRIES.—At a meeting of the Somerset County Council held on Jan. 1st a communication was read from Dr. R. L. Meade-King on behalf of the West Somerset branch of the British Medical Association, asking that a fee might be paid for giving information to coroners when no inquest was held. It was decided that a reply should be sent stating that the county council had no power to pay any such fee.

MEDICAL MAGISTRATES.—Mr. J. C. Davies, L.R.C.P. Lond., M.R.C.S. Eng., D.P.H. Durh., of Ruabon, Denbighshire, has been appointed a magistrate for the county of Denbigh.—Mr. Harold J. Hutchens, L.R.C.P. Lond., M.R.C.S. Eng., of Colmslie Hospital, Bulimba, has been appointed a justice of the peace within the Colony of Queensland.—Mr. Norman Hay Forbes, F.R.C.S. Edin., of Tunbridge Wells, has been appointed a magistrate for the county of Kent.

SHORTHAND FOR MEDICAL STUDENTS.—The Society of Medical Phonographers offers for competition among registered medical students in the United Kingdom a first and a second prize, of the value of £5 and £3 respectively, for proficiency in the groundwork of phonetic shorthand (phonography). The examination will have for its chief object legibility, accuracy, and neatness of writing rather than speed, and will consist of two simple tests: (*a*) the ability to read at sight a passage of a few hundred words printed in a freely vocalised style of shorthand; and (*b*) the ability to write shorthand at a low rate of speed (60 words per minute) and to produce a correct longhand transcript of the passage so dictated. In this test the quality of the shorthand note as well as the correctness of the transcript will be taken into account. The passage used in each test will consist of some straightforward medical matter. The examination will be held early in May, 1901, simultaneously in London, Edinburgh, and Dublin and at any provincial medical school in the United Kingdom at which not fewer than three candidates shall offer themselves. Intending candidates are requested to send in their names at as early a date as possible to "The Examination Secretary, care of Messrs. Pulman and Sons, Thayer-street Manchester-square, London," who will inform them in due course as to the precise date and place of examination at each centre. There are no examination fees. The latest date for receiving names will be April 15th.

BRITISH MEDICAL BENEVOLENT FUND.—Mr. Edward East, of 26 Linden-gardens, W., is receiving and distributing clothing of all sorts. He desires us to state that the fund particularly wants quantities of warm clothing and blankets for men, women, and children.

MEMORIAL TO A MEDICAL MISSIONARY.—On Sunday, Jan. 6th, a memorial tablet to the late Charles Watt Morrison and Samuel Donaldson Cowan, M.A., M.B., C.M., was unveiled at the Young Men's Christian Association, Kirkintilloch, by Mr. R. Hudson, J.P. The tablet bears the following inscription: "Charles Watt Morrison, died at New York, U.S.A., Dec. 28th, 1897, aged 32. Samuel Donaldson Cowan, M.A., M.B., C.M.; died at sea, Sept. 14th, 1899, aged 29. In loving memory of Charles Watt Morrison, missionary teacher, and Samuel Donaldson Cowan, M.A., M.B., C.M., medical missionary, loyal and faithful members of Kirkintilloch Y.M.C.A., who went forth at the call of God to labour among the heathen at Old Calabar, West Coast of Africa. 'Good Soldiers of Jesus Christ.'"

FREEMASONRY.—The *Rahere Lodge, No. 2546.*—A meeting of this lodge was held at Frascati's Restaurant, Oxford-street, W., on Jan. 8th, the W. M. Bro. Walter Gripper in the chair. Messrs. L. E. Whitaker and H. S. Beadles were initiated into Freemasonry, and Bro. R. H. Wellington was raised to the third degree by the W. M., whilst Bros. Hepburn and Bokenham were passed to the second degree by Bro. Phin. S. Abraham, S.W. W. Bro. Brodie was nominated a steward at the forthcoming festival of the Royal Masonic Benevolent Institution and a grant of 10 guineas was made from the lodge funds in aid of this charity.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

HOSPITALS AND SCIENTIFIC RESEARCH.

THE National Anti-Vivisection Society has issued a list of the metropolitan hospitals which have among their medical or surgical officers one or more who hold licences from the Secretary of State for the Home Department authorising them to perform experiments upon living animals, together with a list of those which are "entirely free from any connexion with vivisection" as a "guide for the charitable in the disposition of their gifts and bequests." The *Times* makes the following witty comment upon the list. "The list, nevertheless, may possibly serve a useful purpose, the very reverse of that intended by its compiler. No reasonable person can doubt that the hospitals denounced by Mr. Coleridge are among the very best in existence. If intending donors will act in direct opposition to his suggestions, they will have the greatest attainable prospect of devoting their money to good and useful purposes."

ACTION UNDER THE DENTISTS ACT.

AN action of an involved character under the Dentists Act was heard at Bow-street Police-court on Jan. 4th. The British Dental Association prosecuted one named "Scott Russell." In the course of the evidence it appeared that the business belonged to Mr. W. B. Trick, whose name appeared on the Dental Register, and who carried on the practice under the name of "Scott Russell." Mr. W. B. Trick left the management in the hands of his cousin, Mr. W. H. Trick, who although qualified had not taken the trouble to get himself registered. The British Dental Association subsequently withdrew the summons. In the course of the evidence given it was shown that Mr. W. H. Trick had held himself out to be Mr. Scott Russell, while on a door-plate was the following announcement: "Scott Russell, late W. H. Trick, L.D.S. Eng., Dental Surgeon." The case seems to open up a most important point—namely, whether members of the medical and dental professions have the right to practise under other names.

ACRODYNIA.

To the Editors of THE LANCET.

SIRS,—Can you or any of your readers inform me where I could find a full account of the epidemic of "acrodynia" which occurred in Paris in the year 1828 and how it can be diagnosed from chronic arsenical poisoning? I am, Sirs, yours faithfully,

H. L. GORDON, L.R.C.P. & S. Edin., L.F.P. & S. Glasg.

Accrington, Jan. 8th, 1901.

*** Reference may be made to the following:—Clairat (L.): Considérations sur la Maladie Épidémique que règne à Paris, 4to, Paris, 1829. Miramond (P. R.): Sur l'Affection Epidémique qui s'est manifestée à la Caserne de la rue de l'Oursine dans le mois de Septembre, 1828, 4to, Paris, 1829. Rochette (J. G. F.): De l'Acrodynie, 4to, Paris, 1871. Rue (A.): Essai sur la Maladie qui a régné épidémiquement à Paris, depuis le commencement de l'année 1828, 4to, Paris, 1829. Vidal (E.) et Leloir (H.): Traité des Maladies de la Peau, article Acrodynie Paris, 1864. Stedman (T. L.): Twentieth Century Practice, vol. v., p. 835, London, 1896.—ED. L.

A HASTY CRITIC.

THE *Bristol Mercury* of Dec. 28th states that "that bitterly trade unionist journal THE LANCET is in a state of mind because a Bill is before the Italian Parliament to prevent any medical men practising who are not registered in Italy." Our contemporary adds that "we can see no 'malignant jealousy' in the course which the Italian Legislature is taking." THE LANCET is in the same position. Our correspondent in Rome used the words "malignant jealousy," we did not; and he applied them—we think aptly—to a few bigoted agitators and not to the Italian Legislature. We think that the *Bristol Mercury* might do us the honour of reading our columns before diagnosing our state of mind or calling us names. By the way, we see that the *Bristol Mercury* allows that "it is undoubtedly unfair to dispossess those who are already in practice." This is just what the Santini Bill proposes to do, and the commission appointed to examine the draft of this Bill has rejected an amendment of the Minister for Foreign Affairs, Visconti Venosta, proposing that existing rights should be respected.

THE MEDICAL MAN AND THE HERBALIST.

To the Editors of THE LANCET.

SIRS,—I shall be most happy for information with regard to the following case which has this day happened to me. I have been attending daily a little girl since the 31st ult. for an attack of measles with broncho-pneumonia as a complication. The little patient has made very satisfactory progress in every respect and has manifestly bridged over the worst phase of her illness since last Saturday. In the face of this improvement the father, who, I may say, is very averse to our "poisonous medicines," thought he could do no better than to write to a certain "herbalist" in whom he

has, and has always had, the most implicit confidence, with the natural result that the herbalist has already sent since last Friday 10 large bottles of some of his concoctions, and this without having seen the patient in any shape or form. The medicine was shown to me this morning by the mother of the child. Immediately this was told to me I declined to have anything further to do with the case, and have given the mother distinctly to understand that I cease my attendance from this date, and should anything of a serious nature occur she must look to the "herbal specialist" and not to me for a remedy.—I am, Sirs, yours faithfully,

Bexhill-on-Sea, Jan. 8th, 1901. R. DE MARTINI.

*** Our correspondent did right to withdraw from the case.—ED. L.

A FEARSOME STORY.

THE *Morning Leader's* "own correspondent" sends a fearsome story from Vienna, dated Jan. 1st, to the effect that a "strike of doctors has occurred at Cracow, owing to an attempt of the local authorities to introduce a legal tariff for medical fees." The medical men, we learn, declare that they will deprive the town of medical aid until they are allowed to charge their own prices. The staff of the hospital have refused to treat a child who had been run over by a tram-car and fearfully mangled, and the medical men are holding meetings at one of which a "doctor on the staff of the hospital said that if driven to desperation they would wreak a fearful vengeance by letting loose the germs of bubonic plague and other dread diseases in all parts of the town"—forgetting, apparently, in the foolish excess of wrath that a disease germ is as likely to attack a medical man as anyone else. This trick has already been played in fiction, and we think that the new author of the story has about as much claim as the author of "Les Morticoles" to veracity. The public are not likely, we trust, to give the slightest credence to such rubbish, but none the less we must protest against the dissemination of such libels upon our profession.

WANTED—A HOME.

To the Editors of THE LANCET.

SIRS,—I shall be grateful if any of your readers can give me the address of a home in which a young man of good education, not of the working-class, suffering from advanced tuberculosis, pulmonary, renal, and intestinal, can be received on payment of about 30*s.* per week. He is not bedridden and not a case for a home for the dying, but I am anxious to get him settled in some place where he will be looked after when he is too ill to live in lodgings.

I am, Sirs, yours faithfully,

119, Upper Richmond-road, Putney, S.W., Jan 6th, 1901. J. GAY.

A.D. 2001.

THE *Scarborough Post* has issued a number dated Jan. 1st, 2001. The editor says that the object of the number "is to present a twenty-first century newspaper as we think it probably will be." Having read the very much "advance" copy of the *Scarborough Post* we congratulate our contemporary upon the imagination displayed, but if the world is to be as the *Scarborough Post* forecasts we are glad to think that in the natural course of events we shall not be alive in A.D. 2001. The prospect of electricity at 1*d.* per unit is fascinating, but the people of 2001 are to be annoyed by street music of a new and terrible sort, for the advent of the motor organ is prophesied. Segregation colonies will be established in the Pacific for the congenital criminals and other undesirables, and in these colonies the sexes will be divided so that the taint cannot be handed on to succeeding generations. Here we have the germ of a truly progressive idea, but humanitarianism would shrink from so drastic a course. Vagrants and tramps are to cease to exist in England in 2001, from which it can be guessed that England at that date is Tory and Protectionist, so that the soil will give occupation to all. We congratulate the editor of the *Scarborough Post* upon his idea, and we agree with him that a paper published in 1801 and composed entirely of a guess made at that date of what 1901 would be like, would be just now exceedingly interesting reading. An historical brochure, a flimsy attempt to forecast at the beginning of the nineteenth century the political conditions and relations of Great Britain and the European Powers at the end of the century, was, we believe, recently published and was comically incorrect in every way.

OPHTHALMIC STUDIES IN PARIS, BERLIN, AND VIENNA.

To the Editors of THE LANCET.

SIRS,—I should feel obliged if any of your readers would give me information on the following points:—(1) The cost, times, &c., of special courses on the eye for English-speaking medical men at Paris, Berlin, and Vienna; (2) the addresses of some good boarding-houses, not English, in these cities. I am, Sirs, yours faithfully,

Jan. 9th, 1901. HOMER.

IMPROVED ELECTRIC WIRING.

APROPOS of our remarks on the dangers of electric lighting in our issue of Nov. 24th, 1900, p. 1518, we have received from the Conduit and Insulation Company, Limited, of Ormond House, 63, Queen Victoria-street, E.C., a specimen of steel armoured insulating conduit. This consists of a steel tube ingeniously lined with insulating material. It is maintained that all electric wires should be inclosed in a tube of this kind and then absolute safety would be guaranteed. We ourselves have suggested that some such method seems to be needed in view of the strange, not to say dangerous, things which happen when the wires are simply contained in wooden cases and when the cases themselves are in precarious places. It is certain that better provision must be made to prevent the leakage of current on the electric railways, for it is stated that the increasing employment of electricity as a motive power is threatening to destroy our gas and water mains. We suppose that when the rupture of a big gas main is effected and a chance electric spark ignites the escaping gas, perhaps with a disastrous explosion, some pressure will be brought to bear up n those who employ electric power without regard to the best means of preventing the escape of waste current.

"THE CHOICE OF A CEPHALOTRIBE."

To the Editors of THE LANCET.

SIRS,—In answer to G. P.'s letter in THE LANCET of Jan. 5th (p. 75) asking for advice in the choice of a cephalotribe I should like to say that I have performed the operation of craniotomy many times and I have tried several kinds of cephalotribe, including one of my own design. The conclusion I have come to is that all the cephalotribes on the market are useless instruments. The very best instrument I have used—and I wish for no better—is Winter's modification of Auvard's combined cranioclast and cephalotribe. With this instrument craniotomy becomes a much simpler and easier operation. Dr. Jellett describes the instrument in his book on the Practice of Midwifery.

I am, Sirs, yours faithfully,

Jan. 9th, 1901. CEPHALOTRIBE.

R. M. O.—"A Text-Book of Nursing," by C. S. Weeks-Shaw (London and New York: Edward Arnold. 1896. Price 3*s.* 6*d.*).—Lectures on Medicine to Nurses, by Herbert Cuff, M.D. Lond., F.R.C.S. Eng. (London: J. & A. Churchill. 1896). The latter book is, we fancy, a work on purely medical nursing.

F.R.C.S. Ed.—Medical graduates of Brussels University, doubly qualified in Great Britain and on the Medical Register, are always held to be right in styling themselves "Dr."

H. M. D.—The question might be asked of the advertisers, but on the face of the advertisement the answer is No.

Mr. W. Parkinson Bothamley is thanked for his letter. We hope to give the subject attention.

Mr. Archibald Kidd.—The reports are published by Messrs. P. S. King and Son, London.

Mr. G. A. Brown is thanked for bringing the disgraceful matter to our notice.

Osiris.—Yes.

COMMUNICATIONS not noticed in our present issue will receive attention in our next.

METEOROLOGICAL READINGS

(Taken daily at 8.30 a.m. by Steward's Instruments.)

Medical Diary for the ensuing Week.

OPERATIONS.

METROPOLITAN HOSPITALS.

MONDAY (14th).—London (2 P.M.), St. Bartholomew's (1.30 P.M.), St. Thomas's (3.30 P.M.), St. George's (2 P.M.), St. Mary's (2.30 P.M.), Middlesex (1.30 P.M.), Westminster (2 P.M.), Chelsea (2 P.M.), Samaritan (Gynæcological, by Physicians, 2 P.M.), Soho-square (2 P.M.), Royal Orthopædic (2 P.M.), City Orthopædic (4 P.M.), Gt. Northern Central (2.30 P.M.), West London (2.30 P.M.), London Throat (2 P.M.).

TUESDAY (15th).—London (2 P.M.), St. Bartholomew's (1.30 P.M.), Guy's (1.30 P.M.), St. Thomas's (3.30 P.M.), Middlesex (1.30 P.M.), Westminster (2 P.M.), West London (2.30 P.M.), University College (2 P.M.), St. George's (1 P.M.), St. Mary's (1 P.M.), St. Mark's (2.30 P.M.), Cancer (2 P.M.), Metropolitan (2.30 P.M.), London Throat (2 P.M. and 6 P.M.), Royal Ear (3 P.M.), Samaritan (9.30 A.M. and 2.30 P.M.).

WEDNESDAY (16th).—St. Bartholomew's (1.30 P.M.), University College (2 P.M.), Royal Free (2 P.M.), Middlesex (1.30 P.M.), Charing-cross (3 P.M.), St. Thomas's (2 P.M.), London (2 P.M.), King's College (2 P.M.), St. George's (Ophthalmic 1 P.M.), St. Mary's (2 P.M.), National Orthopædic (10 A.M.), St. Peter's (2 P.M.), Samaritan (9.30 A.M. and 2.30 P.M.), Gt. Ormond-street (9.30 A.M.), Gt. Northern Central (2.30 P.M.), Westminster (2 P.M.), Metropolitan (2.30 P.M.), London Throat (2 P.M.), Cancer (2 P.M.)

THURSDAY (17th).—St. Bartholomew's (1.30 P.M.), St. Thomas's (3.30 P.M.) University College (2 P.M.), Charing-cross (3 P.M.), St. George's (1 P.M.), London (2 P.M.), King's College (2 P.M.), Middlesex (1.30 P.M.), St. Mary's (2.30 P.M.), Soho-square (2 P.M.), North-West London (2 P.M.), Chelsea (2 P.M.), Gt. Northern Central (Gynæcological, 2.30 P.M.), Metropolitan (2.30 P.M.), London Throat (2 P.M.), St. Mark's (2 P.M.), Samaritan (9.30 A.M. and 2.30 P.M.).

FRIDAY (18th).—London (2 P.M.), St. Bartholomew's (1.30 P.M.), St. Thomas's (3.30 P.M.), Guy's (1.30 P.M.), Middlesex (1.30 P.M.), Charing-cross (3 P.M.), St. George's (1 P.M.), King's College (2 P.M.), St. Mary's (2 P.M., Ophthalmic 10 A.M.), Cancer (2 P.M.), Chelsea (2 P.M.), Gt. Northern Central (2.30 P.M.), West London (2.30 P.M.), London Throat (2 P.M. and 6 P.M.), Samaritan (9.30 A.M. and 2.30 P.M.).

SATURDAY (19th).—Royal Free (9 A.M. and 2 P.M.), Middlesex (1.30 P.M.), St. Thomas's (2 P.M.), London (2 P.M.), University College (9.15 A.M.), Charing-cross (2 P.M.), St. George's (1 P.M.), St. Mary's (10 P.M.), London Throat (2 P.M.).

At the Royal Eye Hospital (2 P.M.), the Royal London Ophthalmic (10 A.M.), the Royal Westminster Ophthalmic (1.30 P.M.), and the Central London Ophthalmic Hospitals operations are performed daily.

SOCIETIES.

MONDAY (14th).—MEDICAL SOCIETY OF LONDON.—8.30 P.M. Dr. H. Walsham and Dr. C. Beale: On the Diagnostic Value of Skiagraphy in Chest Diseases, with Skiascopic and Lantern Demonstrations.

TUESDAY (15th).—PATHOLOGICAL SOCIETY OF LONDON (20, Hanover-square, W.).—8.30 P.M. A Card Specimen will be shown by Dr. O. K. Williamson. Mr. S. G. Shattock: Chondro-sarcoma of Tibia associated with Pendulous Bodies.—Dr. M. Fletcher: Chronic Cholangitis in a Child.—Dr. H. D. Rolleston: Primary Carcinoma in a Cirrhotic Liver.—Mr. P. de Santi: Adenomatous Papilloma of the Sigmoid Flexure.—Mr. G. Pernet: The Bacilli of Leprosy, are they Intra- or Extra-cellular?

CHELSEA CLINICAL SOCIETY (Holy Trinity Parish Hall, Pavilion-road, Sloane-square, S.W.).—8.30 P.M. Paper:—Mr. C. A. Morris: Tubal Pregnancy.—Dr. Blumfeld: After-effects of Anæsthetics.—Dr. C. J. Harrison: Acute Rheumatism of Childhood.

WEDNESDAY (16th).—ROYAL MICROSCOPICAL SOCIETY (20, Hanover-square, W.).—8 P.M. The President: Annual Address.

ROYAL METEOROLOGICAL SOCIETY (Institute of Civil Engineers, Gt. George-street, Westminster, S.W.).—7.30 P.M. Ordinary Meeting. 7.45 P.M. Annual General Meeting. Report of the Council. Election of Officers and Council for the ensuing year. Address:—Dr. C. T. Williams (President): The Climate of Norway and its Factors (illustrated by lantern slides).

FRIDAY (18th).—EPIDEMIOLOGICAL SOCIETY OF LONDON (11, Chandos-street, Cavendish-square, W.).—8.30 P.M. Meeting.

SOCIETY FOR THE STUDY OF DISEASE IN CHILDREN (East London Hospital for Children, Shadwell, E.).—5.30 P.M. Cases will be shown by Dr. M. Fletcher (introduced), Mr. H. B. Robinson, Dr. G. Little (introduced), and Mr. F. C. Abbott. Papers:—Dr. L. Guthrie: A Case of Chronic Interstitial Nephritis in a Girl aged seven years.—Mr. S. Spokes: The immediate Regulation of Children's Teeth, with Models to illustrate cases Before and After Treatment.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

MONDAY (14th).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chenies-street, W.C.).—4 P.M. Dr. T. Colcott Fox: Consultation. (Skin.)

TUESDAY (15th).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chenies-street, W.C.).—4 P.M. Sir W. Broadbent: Consultation. (Medical.)

GRESHAM COLLEGE (Basinghall-street, E.C.).—6 P.M. Dr. E. Symes Thompson: The Organs of Perception.

WEDNESDAY (16th).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chenies-street, W.C.).—4 P.M. Mr. J. Cantlie: Consultation. (Surgical).

GRESHAM COLLEGE (Basinghall-street, E.C.).—6 P.M. Dr. E. Symes Thompson: Training of Perceptions.

THURSDAY (17th).—CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL (Gray's Inn-road, W.C.).—5 P.M. Mr. Lennox Browne: Intra-Nasal Obstructions; Soft—Hypertrophies of the Turbinals, Polypi, &c.

MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chenies-street, W.C.).—4 P.M. Mr. J. Hutchinson: Consultation. (Surgical.)

CHARING-CROSS HOSPITAL.—4 P.M. Mr. Gibbs: Surgery in South Africa. (Post graduate Course.)

THE HOSPITAL FOR SICK CHILDREN (Gt. Ormond-street, W.C.).—4 P.M. Dr. Colman: Demonstration of Selected Cases.

GRESHAM COLLEGE (Basinghall-street, E.C.).—6 P.M. Dr. E. Symes Thompson: Disorders of Perception.

FRIDAY (18th).—MEDICAL GRADUATES' COLLEGE AND POLYCLINIC (22, Chenies-street, W.C.).—4 P.M. Mr. H. Spicer: Consultation. (Eye.)

GRESHAM COLLEGE (Basinghall-street, E.C.).—6 P.M. Dr. E. Symes Thompson: Travel in Relation to Disordered Perceptions.

EDITORIAL NOTICES.

It is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITORS," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

Lectures, original articles, and reports should be written on one side of the paper only, AND WHEN ACCOMPANIED BY BLOCKS IT IS REQUESTED THAT THE NAME OF THE AUTHOR, AND IF POSSIBLE OF THE ARTICLE, SHOULD BE WRITTEN ON THE BLOCKS TO FACILITATE IDENTIFICATION.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET *should be addressed "To the Manager."*

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES.

THE INDEX TO THE LANCET.

THE Index to Vol. II. of 1900, which was completed with the issue of Dec. 29th, and the Title-page to the Volume were given in THE LANCET of Jan. 5th.

VOLUMES AND CASES.

VOLUMES for the second half of the year 1900 will be ready shortly. Bound in cloth, gilt lettered, price 18*s.*, carriage extra.

Cases for binding the half-year's numbers are now ready. Cloth, gilt lettered, price 2*s.*, by post 2*s.* 3*d.*

To be obtained on application to the Manager, accompanied by remittance.

TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, W.C., are dealt with by them? Subscriptions paid to London or to local newsagents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and *not* to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will ensure regularity in the despatch of their Journals and an earlier delivery than the majority of Agents are able to effect.

The rates of subscriptions, post free, either from THE LANCET Offices or from Agents, are:—

FOR THE UNITED KINGDOM.		TO THE COLONIES AND ABROAD.	
One Year	£1 12 6	One Year	£1 14 8
Six Months	0 16 3	Six Months	0 17 4
Three Months	0 8 2	Three Months	0 8 8

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London and Westminster Bank, Westminster Branch") should be made payable to the Manager, MR. CHARLES GOOD, THE LANCET Office, 423, Strand, London, W.C.

Communications, Letters, &c., have been received from—

A.—Association for Pure Vaccine Lymph, Lond.; A. M. L. R.; Mons. J. Astier, Asnières, France; Messrs. Arnold and Sons, Lond.; Messrs. Allen and Hanburys, Lond.; A. A.

B.—Mr. H. L. Barnard, Lond.; Bolton Infirmary, Secretary of; Dr. L. Blanc, Aix-les-Bains; Birmingham General Hospital, House Governor of; Messrs. Brown, Gould, and Co., Lond.; C. Two Clinical Lectures
ON
ENLARGEMENT OF THE PROSTATE.

Delivered at the Medical Graduates' College and Polyclinic

BY P. J. FREYER, M.A., M.D., M.CH.,
SURGEON TO ST. PETER'S HOSPITAL FOR STONE AND URINARY DISEASES.

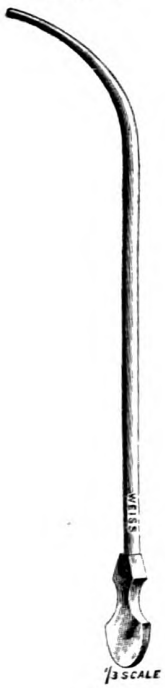
LECTURE II.[1]

Delivered on Nov. 9th, 1900.

GENTLEMEN,—Passing on to the treatment of enlargement of the prostate, you are aware that in this field of research considerable activity has been displayed by surgeons in recent years as regards operative interference. Holding, as I do, that in certain selected cases of this disorder an operation of some kind is advisable, and in a small minority imperative, to save the patient's life or ameliorate his sufferings, I have no hesitation in saying that in the vast majority the only admissible treatment is judicious and cleanly catheterism combined with careful hygienic living; and that by these means life will be more prolonged and existence rendered more tolerable than by any other.

When enlargement of the prostate is unattended by any symptoms no treatment is necessary. If, however, decided symptoms of obstruction are present, but the bladder contains no "residual" urine, or only an ounce or two, the question arises as to what treatment, if any, is desirable. In such cases I am in the habit of passing a large steel dilator (Fig. 4) as far as the bladder once a week and leaving it in position for 10 or 12 minutes, commencing with a No. 11 or No. 12, English scale, and gradually advancing to No. 15 or No. 16. I entirely concur in the opinion of my colleague, Mr. Reginald Harrison, as to the beneficial effect of this simple procedure. It probably does not stay the progress of the disease, but the periodical introduction of the dilator causes absorption of the gland around the urethra and maintains the patency of the channel, thus staving off for an indefinite period the necessity of having recourse to habitual catheterism. It is customary in cases of this kind in the incipient stage of enlargement to administer ergot with a view to causing reduction of, or retarding the advance of, the outgrowth. I am in the habit of employing the liquid extract of this drug combined with a saline both in hospital and private practice. It is difficult to say definitely whether the ergot has any effect in staying the advance of the enlargement, but it seems to relieve congestion, and patients undoubtedly express themselves as improved under its administration.

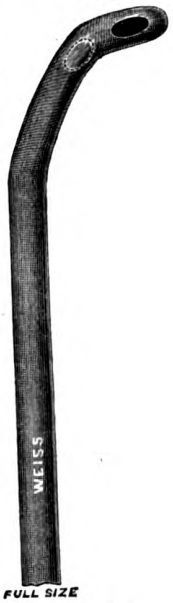
FIG. 4.



It will, as a rule, be unnecessary to have recourse to the habitual use of the catheter till the residual urine amounts to between three and four ounces, but if the frequency of micturition at night is such as to affect injuriously the patient's health through want of sleep it will be desirable to commence earlier. When, however, once about four ounces of residual urine have been reached habitual catheterism must be employed, and the patient enters on what is termed "catheter life," from which he can scarcely ever recede. When the "residual" urine is limited to four ounces or less it will, as a rule, be sufficient to pass the catheter once in the 24 hours and the best time for doing this is at bedtime, so that he may have several hours of sleep afterwards. If six ounces are retained the catheter should be employed twice daily; if eight or 10 ounces three or four times daily. When all power of voluntary micturition is lost the catheter must be used whenever the desire for urination is decidedly felt, generally every four hours or so. On no account should the patient be limited to any specific time within which he should not employ the catheter. The urine should be drawn off before pain or marked discomfort is felt; otherwise congestion of the prostate and bladder resulting in cystitis will be produced.

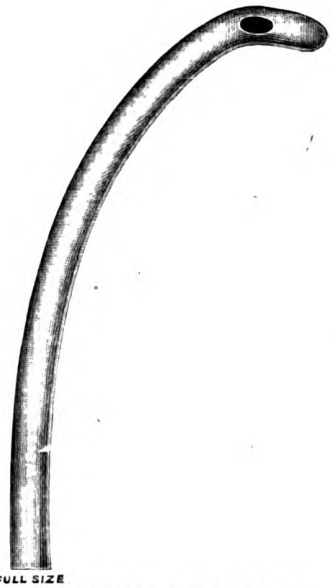
The patient must be taught how to use the catheter, and he should never be without one—that is to say, if he leaves home on a journey or in the course of his ordinary occupation he should always carry one about with him, for he may find at any time that its employment is imperative. Indeed, the sooner the patient recognises that the primary duty of his life is the employment of his catheter the better. A soft coudée catheter, No. 7 to 9E, whichever passes most easily, is, as a rule, the best for habitual employment. The patient, unless very infirm, passes it standing. There is now no danger of his fainting, for the quantity of urine allowed to accumulate is limited, and during the period of instruction in the use of the catheter that he will have undergone at the hands of the surgeon he will have acquired confidence in its use. The instrument is held perpendicularly whilst its end is introduced into the urethra. It is then gradually depressed into the horizontal position as it glides along the canal, over the obstruction and into the bladder, the curved end being directed upwards towards the roof of the urethra. Sometimes a well-polished vulcanised rubber catheter answers best. A timid patient likes it, as less liable to pain him; but if the prostatic urethra is narrowed from pressure of the lateral lobes it is not so easy to introduce as a more rigid instrument. It has also the disadvantage that its walls being stout the channel is comparatively narrow, so that the urine if at all thick will not flow through it readily. On the other hand, as it can be boiled without injury it is readily rendered aseptic, and as it coils up in a small space it can be carried about very easily. A soft and pliant cylindrical catheter will pass readily and answer best when there is no obstruction caused by the middle lobe. When this lobe is much enlarged a bicoudée catheter (Fig. 5) or a well-curved one terminating in a coude (Fig. 6) may be necessary to overcome the obstruction. Formerly it was customary to keep catheters mounted on a well-curved metal stylet ready for use; they are

FIG. 5.



Bicoudée catheter.

FIG. 6.



Well-curved catheter terminating in a coude.

[1] Lecture I. was published in THE LANCET of Jan. 12th, 1901.

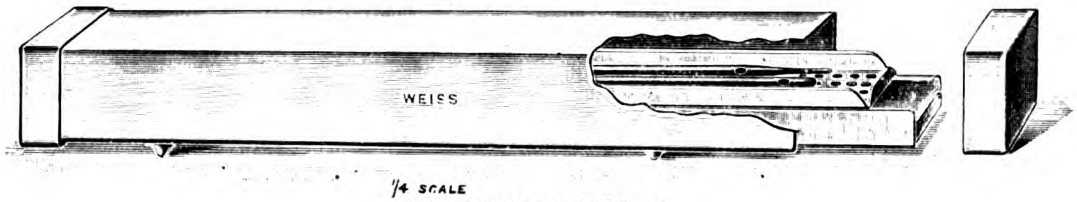
now woven with this curve in their manufacture and retain their shape permanently.

It will be rarely desirable for a patient himself to pass a metal catheter. When circumstances arise requiring its employment the surgeon should be called in. Whatever instrument is employed it must be kept scrupulously clean. The life and comfort of the patient depend not less on the cleanliness of his catheter than on the judicious use of the same. It will not be out of place, therefore, if I here direct your attention to the antiseptic precautions necessary in the employment of urethral instruments in general.

The instruments required for catheterism are of three kinds—metallic, soft rubber, and gum-elastic. The first two are most easily and effectually sterilised by boiling. They should be thoroughly washed and syringed through with soap and warm water and then boiled for 10 minutes, after which they are transferred to boric lotion ready for use. Gum-elastic instruments cannot be boiled without injury. They are best cleansed by washing and syringing them through with soap and warm water and then placing them in a 1 in 40 solution of carbolic acid for 10 minutes, after which they are placed in boric lotion before use. Prolonged application of strong antiseptics renders them rough and useless.

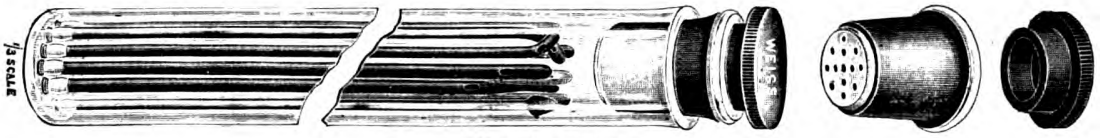
Before introducing an instrument of any kind into the bladder the foreskin and glans should be well washed with soap and water and then swabbed with some weak antiseptic lotion. If there be any discharge from the urethra the anterior part of the canal should be syringed out with warm boric lotion, but otherwise this precaution is unnecessary. Bacteriologists tell us that even the healthy urethra swarms with organisms that cannot be completely got rid of by the most thorough irrigation by antiseptic lotions. so that, theoretically speaking, the introduction of an instrument into the bladder ought to be attended frequently by infection of the urine. Clinical experience, however, teaches us that with the simple precautions indicated this may be avoided.

FIG. 7.



Catheters on trays in air-tight box.

FIG. 8



Glass tube steriliser.

It is useless to lay down an elaborate ritual of urinary asepsis which cannot be followed out in practice by the patient himself. If we only reflect on the frequency with which a man who has entered on catheter life has to pass an instrument and the circumstances under which he has often to do so it is obvious that the means of keeping his catheter aseptic to be efficient must be as simple as possible. Fortunately, in soap and water we have an efficient, convenient, and practical method of cleansing catheters, and this is what most patients have to rely on, and that with impunity. After using the catheter it should be again washed as before, thoroughly dried, and then placed for future use in a corked glass tube or covered dish. The best way of drying soft catheters is by pressing them between folds of lint or gauze in which they may be kept till again required

The powerful antiseptic properties of trioxymethylene, a white powder obtained by evaporation of formol, have recently been taken advantage of on the continent for sterilising gum-elastic catheters. This powder gives off slowly a vapour which is really formol in its gaseous form. If the catheters be placed quite dry on trays in an air-tight box (Fig. 7) with this powder inclosed between folds of lint they are rendered quite aseptic in 24 hours by the vapour given off. Before use they should be placed in boric lotion, as the formol is slightly irritant to the mucous membrane of the urethra. The catheters can also be sterilised in a glass tube fitted with a cork (Fig. 8) containing the powder, which evaporates through a fine grating on its inner aspect. Some patients of mine speak highly of the convenience of this method of rendering catheters aseptic. As lubricants for instruments fresh olive oil, or castor oil, or vaseline may be used. Carbolic acid should not be added; it irritates the mucous membrane if the proportion used be of any strength, and weak carbolised oil has practically no sterilising effect. Guyon's pomade, composed of equal parts of glycerine, powdered soap, and water, with 1 per cent. of phenol or naphthol, is a clean and efficient lubricant.

The general or hygienic treatment is most important. The diet should be light, simple, and nutritious. Vegetables and fruit, particularly baked or stewed apples, should be taken regularly, but tomatoes, asparagus, and rhubard should be avoided, as they act as irritants to the urinary tract. The less stimulants taken the better. The clothing must be adapted to avoid cold; the patient should be swathed in flannel. Sitting on cold or wet seats should be particularly avoided to guard against congestion of the prostate. The daily warm bath, best taken at bedtime, promotes the action of the skin and relieves local congestion about the prostatic region. The most important part of the general treatment is the regulation of the bowels. If they become at all constipated the urinary symptoms are aggravated. Measures should therefore be taken to induce a soft, but not liquid, motion daily. There is nothing better than confection of sulphur or senna or equal parts of both. Aloin, liquorice powder, and the sulphate of soda are useful, or one of the natural bitter saline waters may be taken in the morning. The enema should always be at hand for use in case the other medicines should fail to induce a daily motion. If pain be present an opiate must be given by the mouth, hypodermically, or as suppository. On no account should belladonna be administered whilst the bladder retains any vestige of expulsive power, owing to its paralysing influence on the muscles of that organ. Walking or carriage exercise should be taken daily, rough roads being avoided, but riding on horseback or on a bicycle should be abandoned on account of the shaking or direct pressure on the prostate caused thereby. The patient should as far as possible pursue his ordinary avocation and pleasures, but sexual excitement should be avoided. Many men pass useful and enjoyable lives for 15 or 20 years, or even longer, after entering on the habitual use of the catheter.

COMPLICATIONS AND DIFFICULTIES.

There are certain difficulties and complications incident to catheter life to which I will now direct your attention. When the surgeon is consulted at a comparatively early stage of the disorder, before the residual urine amounts to more than a few ounces, if careful asepsis be employed in the introduction of instruments the entry on catheter life is effected without any constitutional or local disturbance and matters run smoothly. The patient takes to his new existence,

sadly and perhaps unwillingly at first; but he soon bows to the inevitable and is grateful for the relief that surgical art has given him through the agency of the catheter. If, however—and this is what happens in a large proportion of cases that come under observation—through wrong advice, or that timidity about consulting the surgeon that induces elderly men suffering from urinary troubles to put off what they regard as the evil day as long as possible, the symptoms have existed for a long time, there is difficulty and frequency of micturition with some pain, the urine is turbid, possibly fœtid, the patient looks ill and worn-out, and the hypogastric dulness points to the presence of a considerable quantity of residual urine, the case must be regarded as one of considerable gravity. The employment of the catheter for the first time under these conditions is likely to be attended by constitutional disturbances, sometimes of severe character. The examination of such a case had better not be completed in the consulting-room—that is to say, you should defer drawing off the urine till the patient goes home. The examination should be completed in a warm room so that the patient can go to bed immediately afterwards, where he should remain for two or three days in any case, and for a longer period should constitutional disturbances set in. To relieve the distended bladder and then allow the patient out

FIG. 9.

Bottle fitted with nozzle and stopcock for washing out the bladder

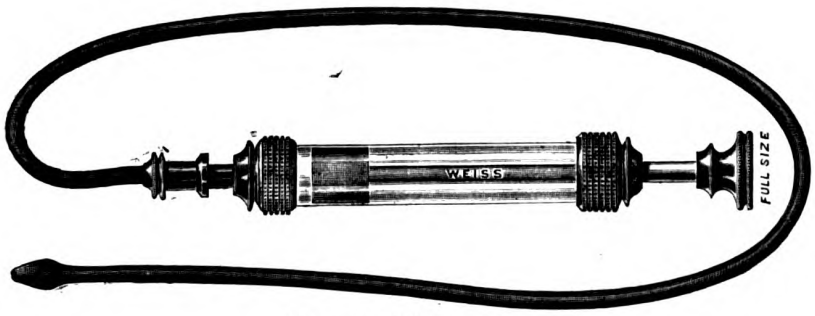
in the cold is injudicious surgery. In hospital practice, when the catheter is employed in a case of this kind in the out-patient department, the man should be at once admitted to bed. If the quantity of residual urine be large only half should be drawn off on first introducing the catheter. The quantity removed should be increased at each subsequent introduction and the bladder not completely emptied for two or three days, during which the patient should be under close observation. If he be too infirm or nervous to pass the catheter himself an experienced nurse should be employed for this purpose.

Urinary fever in connexion with catheterism.—In an advanced case of prostatic disease of this kind the urine, even when clear and acid on the first introduction of the catheter, generally becomes clouded and eventually ammoniacal in the course of a few days, and constitutional symptoms supervene. A rigor will probably occur, or even without this the temperature may rise to 103° or 104° F, profuse perspiration sets in, and, the normal temperature being reached, the fever may not recur. Sometimes more than one attack of this kind occurs, or the fever may be of a continuous character for some days, gradually subsiding; but occasionally the patient sinks into a low typhoid state, with dry, furred tongue, feeble pulse, and great thirst; and if the kidneys are much affected uræmia followed by coma, may set in, resulting in a fatal termination. This fever is variously termed "urinary," "urethral," and "catheter," but its exact cause—whether septic or neurotic—it is impossible with our present knowledge definitely to state. Certainly it occurs under the strictest antiseptic precautions and with the utmost skill in passing the catheter. The general treatment of this fever is similar to that following instrumentation or operation for stricture of the urethra, which has already been described, except that, owing to the advanced age and debility of the patient, it must be more sustaining, stimulants in moderation being allowed. When the urine contains pus the local treatment will be the same as that presently to be described for cystitis.

Cystitis.—Cystitis, as we have already seen, is a common complication of enlarged prostate, so that we must always be prepared to deal with it in its earliest stage. When the urine has a tendency to become cloudy and gives off a fishy, offensive odour the best drug to administer is boric acid, which may be given in 10-grain doses four times daily. A patient of mine, himself a medical man, who for years has been dependent on his catheter, informed me that he found two or three large doses of 25 grains each more effectual in bringing the urine back to its normal condition than repeated small doses; and I have since then frequently verified this experience in practice. If the urine becomes decidedly alkaline the boric acid should be combined with the benzoate of ammonia in 10-grain doses.

When pus forms the bladder must be washed out once or twice daily with disinfectants or astringent lotions. A four-ounce indiarubber bottle fitted with nozzle and stopcock (Fig. 9) is the most convenient apparatus to employ for the purpose. It should be completely filled with the lotion so as to avoid the introduction of air into the bladder. Not more than between two and three ounces should be thrown into the bladder at one time, though it may be necessary to repeat this process several times before the fluid returns unaltered. If, however, the cystitis be severe not more than half an ounce should be introduced, as the bladder walls are under such circumstances extremely intolerant of tension. All lotions should be used warmed to 100° F. For cleansing the bladder the most simple and useful injections are a 1 per cent. solution of boric acid or a teaspoonful of boro-glycerine to four ounces of water. Permanganate of potash solution, commencing with 1 in 5000 and gradually increasing it to 1 in 1000, and perchloride of mercury, 1 in 10,000, make excellent injections. But our sheet-anchor in such cases is nitrate of silver. Commence with a very weak solution, 1 in 4000, gradually increasing the strength to 1 in 750. It is rarely that the bladder will tolerate a stronger solution. I have

FIG. 10.



Olivary-tipped Guyon syringe.

found solution of resorcin, from 3 to 5 per cent., an excellent injection.

When there is great pain and scalding at the neck of the bladder from local cystitis there is nothing to equal daily "installations" of a strong solution of nitrate of silver. The urine is first drawn off and the bladder is washed out

with boric lotion. The olivary tip of a Guyon's catheter-syringe (Fig. 10) is then passed just through the membranous portion of the urethra and a drachm of the solution, gradually increased from 1 to 3 per cent., is slowly injected. This trickles back into the bladder and is allowed to remain there.

Complete retention of urine.—This is liable to occur suddenly at any time in connexion with enlarged prostate through congestion and swelling of that organ closing up the already narrowed passage. This congestion may be due to cold, sitting on a wet seat, errors in eating and drinking, sexual excesses, an attack of gout, or injury of the prostate by the catheter. Immediate relief of this retention is imperative—by means of the catheter if possible; otherwise by operative interference. It will be inadvisable to waste time by having recourse to hot baths and opium, as in the case of retention from stricture, for the patient being old and the muscular power of the bladder already impaired any delay may culminate in complete and permanent atony of the bladder from over-stretching of its muscles. To relieve the retention catheters of various kinds are employed. First a vulcanised indiarubber catheter should be used. It is astonishing how retention may occur and still little or no resistance be offered to the entrance of a soft instrument of this kind. If this fail a coudée catheter and a well-curved one terminating in a coude (Fig. 6) should be tried in succession. If still unsuccessful a well-curved cylindrical gum-catheter without a stylet should be employed. This instrument may be given any curve at pleasure by dipping it in hot water, bending it into the necessary shape, and plunging it into cold water, when it retains its new form. If we fail with this we employ the same catheter mounted on a stylet. As soon as the end of the instrument reaches the obstruction the stylet is partly withdrawn—a manœuvre which has the effect of causing the end of the catheter to project upwards and forwards, thus frequently entering the bladder. Finally, it may be necessary to employ an ordinary silver catheter or one with a longer curve. The utmost gentleness should be used, force of any kind being avoided, lest a false passage be made or hæmorrhage caused by injury to the prostate. When the middle lobe is the cause of the obstruction and the end of the metal catheter fails to ride over it the point should be directed right or left with a view to hitting off the channel that exists on either side of its neck. If there be much difficulty in introducing a flexible catheter it should be tied in for two or three days, but a metal instrument should, as a rule, be withdrawn. If we fail to introduce any kind of catheter temporary relief may be given by suprapubic aspiration, after which in the course of a few hours a catheter may pass in readily; should this fail it will be necessary to tap the bladder suprapubically by a trocar and cannula and drain it for a time.

If the retention occurs in an early stage of the enlargement, whilst the expulsive power of the bladder is still unimpaired, it is possible that after the use of the catheter for a few days the bladder may return to its normal state and habitual catheterism be unnecessary. But when the disease is far advanced and the retention has existed for some time it is rare for the bladder to regain its contractile power, even partially.

An attack of retention is almost invariably followed by constitutional symptoms, so that the patient will have to remain in bed for several days and the treatment generally will be the same as that already indicated when habitual catheterism is entered upon.

The pre-prostatic pouch.—In cases of enlarged prostate of long standing we may find that before the bladder is fairly entered a pre-prostatic pouch is encountered—that is, a pouch lying in front of the middle lobe and bounded on either side by the lateral lobes of the prostate, and which may permit the beak of a sound to rotate freely within it. I have not observed any reference to this pouch in the text-books, but its existence is of great importance. I have frequently known it to be mistaken for the true bladder cavity. Composed of the dilated prostatic urethra and that portion of the bladder cavity lying in front of the enlarged middle lobe, it, as a rule, contains urine which is drawn off by the catheter, thus giving rise to the impression that the main cavity of the bladder has been entered. Quite recently I was called in consultation to see a case of this kind in which the medical attendant could only draw off about half an ounce of urine each time he introduced the catheter, but without relief to the patient, though the medical attendant felt sure that the bladder was entered. There was great distention of the bladder, felt above the pubes, which was attributed to blood-clot, as the patient was subject to periodic attacks of hæmorrhage. By means of a well-curved coudée catheter I was enabled to effect an entrance to the main cavity of the bladder and to draw off three pints of blood-stained urine, but in doing so I recognised a large pre-prostatic pouch from which the urine had previously been drawn.

A stone may form in this position; I have removed several such calculi, generally by litholapaxy, the cavity being sufficiently large to permit me to work a child's lithotrite in it. I have also known calculi lying in the main cavity of the bladder missed through the surgeon mistaking this pouch for the bladder proper.

Hæmorrhage from the prostate.—Hæmorrhage rarely occurs in the early stages of enlargement of the prostate; but when the disorder is well advanced this is always liable to take place from various causes. The bleeding may arise from the mucous membrane of the bladder or from the prostate. During the early days after entry on the habitual use of the catheter it is liable to occur from the former source, when there is much distension from residual urine previously, due to rupture of the vessels from their being deprived of their accustomed support. As a rule the hæmorrhage is trifling, merely discolouring the urine, without the presence of clots, and requires no particular treatment, the symptoms gradually passing off. Then there may be hæmorrhage as the result of congestion of the prostate after exercise or exposure to wet and cold. This is seldom severe and also passes off with rest. In advanced stages of the disorder there is frequently a varicose condition of the veins on the surface of the prostate, and some hæmorrhage may occur from rupture of these. The bleeding may be so profuse as to distend the bladder. On three occasions I have had to open the bladder suprapubically to turn out an enormous clot filling its cavity. But the most frequent cause of hæmorrhage is injury of the prostate by careless or unskilful use of the catheter or from difficulty in passing the instrument. As a rule, the blood is mixed with the urine; but if the injury be in the prostatic urethra or on the anterior surface of an enlarged middle lobe almost blocking the orifice the blood may flow away quite pure from the urethra.

The treatment consists in perfect rest in bed and the administration of opium. The usual styptic drugs are of little or no avail. The blood-clots may be allowed to dissolve and come away with the urine. Washing them out through a full-sized catheter with a large eye may be tried, but care should be taken that this does not induce further hæmorrhage. When, owing to difficulty in passing the catheter, bleeding occurs on each introduction it is better to tie in a good-sized coudée for a few days. If it gets clogged with clot this may be displaced by gently injecting a little boric lotion from an indiarubber bottle.

Frequent hæmorrhage attended by much pain after exercise in prostatic patients should always give rise to the suspicion of the presence of stone. If a calculus lie in a saccule projecting out from the base of the bladder there may be intense agony during defecation if constipation exist, and the urine will generally be blood-stained afterwards. I have met with two cases of this kind in practice—one in which the symptoms were completely relieved after the stone was removed suprapubically, and the cause of the other was discovered after death. Orchitis is not uncommon in connexion with enlarged prostate, as a result of catheterism or independently of this; and excessive tenderness of one or both testicles is sometimes found, quite apart from any inflammatory state of the organs. Urethritis and balanitis may occur, particularly in patients suffering from diabetes.

OPERATIVE TREATMENT OF ENLARGED PROSTATE.

I shall now direct your attention to the various recognised surgical procedures employed for the disorder under consideration, which may briefly be classified as follows: 1. Radical operations, which aim at removing the obstructing portion of the glands. 2. Operations undertaken for the purpose of inducing atrophy of the prostate—(*a*) castration; and (*b*) excision of the vasa deferentia. 3. Palliative operations—(*a*) drainage of the bladder through the perineum; and (*b*) drainage of the bladder above the pubes.

Radical operations.—Numerous procedures have from time

to time been devised for the removal of the obstructing portion of the enlarged gland. Many of these are obsolete and have merely a historic interest. I shall only refer to the most important operations—those that are of practical value.

1. Division of the prostatic obstruction by the galvano-cautery. Bottini was the originator, as he has been the warmest advocate, of this method. An electrode shaped like a Mercier's sound is introduced into the bladder through the urethra. The beak is turned round and the instrument is withdrawn till it impinges against the obstruction. The current is then turned on and the obstructing portion of tissue is burnt through. This procedure has not been at all extensively employed and at the present time it has few advocates. It is applicable only to a very limited proportion of cases in which the obstruction is confined to the middle lobe, or the bar of hypertrophied tissue extending across the floor of the orifice of the urethra, or the adjacent portion of the trigone. But the chief objection to its employment lies in the fact that the operation is done in the dark, thus rendering it impossible to gauge accurately the extent of destruction done by the cautery. Wishart and Watson employed the galvano-cautery for the same purpose as Bottini, through a perineal opening into the urethra at the apex of the prostate.

2. Removal of a median growth through a perineal opening into the urethra by means of forceps or instruments constructed to punch out a portion of the growth. This also is an operation with a very limited range of application. I have from time to time employed this method in suitable cases, and have on two or three occasions removed a pedunculated prostatic outgrowth, either accidentally or by design, when performing perineal lithotomy.

3. Suprapubic prostatectomy. Though this operation had previously been performed by several surgeons it is to McGill, who brought it prominently before the profession in this country in 1888 with a series of cases, that it owes its present position. The varieties of prostatic enlargement for which this operation is suitable are (1) enlargements of the middle lobe, whether sessile or pedunculated, projecting into the cavity of the bladder, or forming a bar across the floor of the inner orifice of the urethra; (2) enlargements of one or both lateral lobes, forming prominent tumours in the bladder; and (3) hypertrophied prostatic tissue forming a ring or collar around the inner orifice of the urethra and partially closing it up. The preliminary stage of this operation—viz., the cystotomy—is identical with that for the removal of vesical stone or tumour by the suprapubic method. The employment of the rectal bag is a matter of taste. Personally I have almost completely discarded it as cumbersome and unnecessary, though I habitually used it for some years after its introduction by Petersen. As soon as the bladder is opened the forefinger of the left hand is introduced and a general survey of its cavity is made. By this means the position, shape, size, and general character of the prostatic outgrowth are ascertained. If the middle lobe be pedunculated it can be removed either by clipping the pedicle through, flush with the trigone, by means of scissors curved on the flat, or by twisting it off by the aid of forceps. A sessile middle lobe is removed by notching the mucous membrane and submucous tissues on either side of the growth, which is then twisted off by forceps. A prostatic bar or lower portion of hypertrophied collar is similarly removed or cut away by means of Jessop's forceps. A prominent lateral lobe is first grasped by strong catch forceps to render it steady. The mucous membrane at the most projecting part is then snipped by scissors. The opening thus made is enlarged by the finger-nail and the tip of the finger is introduced. The tumour is enucleated by slowly and carefully separating it from the surrounding tissues. Indeed, in the removal of prostatic enlargements suprapubically the scissors should as a rule be merely employed to snip the mucous membrane, the enucleation being accomplished by the finger-point. In this manner hæmorrhage is reduced to a minimum. Prostatic outgrowths prominently projecting into the bladder consist, as a rule, of more or less distinctly encapsuled tumours covered by the mucous membrane. The hypertrophied collar sometimes assumes a nodulated or beaded aspect, and if the mucous membrane covering it be snipped with scissors these small tumours can be enucleated by the finger-nail. As a rule the hæmorrhage is not severe and can be controlled by irrigation with hot boric lotion. If at all profuse the thermo-cautery should be applied to the bleeding points through a speculum, or the tincture of the perchloride of iron on a sponge. The finger of an assistant placed in the rectum will be of great aid, thus rendering the tumour in the bladder steady and more prominent. Sometimes the enucleation can be best effected by the surgeon introducing one or two fingers of his right hand into the rectum, whilst the finger of the left hand is in the bladder. The drainage of the bladder and after-treatment are the same as after suprapubic cystotomy for stone or tumour.

This is undoubtedly the most valuable of the radical procedures employed for the removal of prostatic outgrowths—that which is most commonly applicable, most easily accomplished, and most thorough in its results. I have performed this operation on several occasions and with considerable success. In one instance I removed both lateral lobes projecting into the bladder, each of the size and shape of half a large pear, the whole weighing three ounces. In another there were distinct encapsuled tumours corresponding to the three lobes, weighing two ounces, which were enucleated quite readily. Both these operations were thoroughly successful, the patients getting complete control over micturition, which was unattended by any symptoms.

Unfortunately, in a few of my cases the bladder did not regain any of its expulsive power even after the obstruction was thoroughly removed, owing to the existence of complete atony of the muscles of the bladder from prolonged obstruction or general sclerosis of the bladder walls. The removal of the growths was, however, followed by subsidence of the most urgent symptoms and rendered the introduction of the catheter easy.

4. Perineal prostatectomy by Dittel's method. This operation consists in removing a wedge-shaped portion from the under surface of one or both lateral lobes with a view to relieve the pressure on the urethra. This is accomplished through an incision extending from the median raphe round the sphincter ani to the tip of the coccyx. The ischio-rectal fossa is opened up and by dissection the rectum is separated from the prostate, which is exposed and a wedge-shaped portion is removed from it. By extending the dissection in front a little beyond the middle line the other lobe of the prostate can be exposed and similarly dealt with. An essential feature is that the bladder and urethra be left intact. This operation does not appear to have been performed in many instances and the records of cases are not very encouraging, fistulæ remaining in some of them owing to the urethra or bladder having been opened during the procedure and imperfect results being obtained in others.

5. Nicoll has modified this operation by performing a preliminary suprapubic cystotomy. This is done for the purpose of introducing a finger into the bladder with a view to pushing the prostatic tumour into the perineal wound, thus facilitating its removal, and at the same time obviating the opening of the mucous membrane of the bladder or urethra.

6. In a communication to the Medical Society of London made in March, 1900, I described, by means of an illustrative case, a new method of performing perineal prostatectomy in which advantage is taken of Dittel's perineal incision; but Nicoll's objects are attained by a much less serious proceeding than suprapubic cystotomy—viz., by a preliminary perineal opening into the urethra.

A gentleman, aged 59, sent by Dr. Richard Heath, of St. Leonards-on-Sea, consulted me on October 11th, 1889, suffering from the following symptoms: increased frequency of micturition, averaging about ten or eleven times by day and seven or eight times by night; difficulty in starting the stream, necessitating much straining to effect this; he finds that when he places his hand on the hypogastric region and pushes the abdomen upwards the stream starts more readily. Diminished force of the stream. Dribbling at the end of micturition. Sometimes the stream is intermittent. The urine is clear, as a rule; some eight months ago it was very dark in colour, but patient cannot say if it contained blood. Pain and discomfort behind the glans during micturition, and discomfort above the pubes before the act. The symptoms have existed three years and have been gradually growing worse. At first they were more troublesome at night, but latterly they have been as bad in the daytime. They are increased by exercise, particularly in walking. I sounded the patient, but could find no stone. There was some difficulty in passing the instrument over the enlarged prostate. Residual urine four and a half ounces; trace of albumin. Per rectum there was a tumour felt in the right side of the prostate, twice the size of a walnut, very dense throughout, with a nodule of intense hardness, which was very painful on pressure. This nodule felt like a stone embedded in the prostate. The left lobe of the prostate was scarcely enlarged and quite soft. On the 17th I made a cystoscopic examination, the patient being anæsthetised by Dr. Dudley Buxton, and Mr. Victor Horsley being present in consultation. The right lobe of the prostate was seen to be enlarged and projecting into the bladder, the size of a walnut, irregularly nodulated, and of a dark-brown colour. The left lobe was not visible in the bladder, which, generally, presented a healthy appearance,

except that the mucous membrane was trabeculated, the result of constant straining and backward pressure of urine. After consultation exploration of the bladder by a perineal urethrotomy was decided on, and this was carried out next day. The urethra was opened in front of the prostate on a staff. On passing my finger through the opening I found a round, prominent mass, involving the right lobe of the prostate, projecting into the bladder, but no stone could be detected. On inserting the forefinger of my other hand into the rectum the hard nodule was felt as before and the tumour clearly defined, rounded, and intensely hard, the left lobe of the prostate being almost normal. After consultation with Mr. Horsley we determined to remove the tumour perineally. A crescentic incision about four inches long was made from the median raphe at the lower end of the urethral wound backwards round the anus to the coccyx on the right side. The dissection was carried deep into the ischio-rectal fossa, the rectum being drawn inwards by a broad retractor. The left forefinger was passed through the urethral wound into the bladder and hooked round the tumour, which was pressed out into the wound, and thus came well into view. The capsule of the prostate was incised and peeled off by means of an elevator. The tumour, which involved the whole of the right lobe of the prostate, was thus removed piecemeal by cutting forceps and curved scissors, only a thin layer being left to support the mucous membrane of the bladder and prostatic urethra, which was left intact. There was very little bleeding, and this was controlled by forcipressure, no vessels being ligatured. On completion of the operation a soft-rubber perineal tube was passed through the urethral opening into the bladder and retained there by a suture, and on this a rubber drainage-tube was fixed to convey the urine to a vessel beneath the bed. The large gaping wound in the ischio-rectal fossa was packed with iodoform gauze and the usual dressings applied. The perineal tube was kept in for six days, during which time the whole of the urine passed through it, not a drop escaping beside the tube, thus obviating any chance of infection of the deep ischio-rectal wound till it had partly filled up and was covered by healthy granulations. The temperature rose to 100° F. one night, after which it did not go above 99° F. After a fortnight the urine began to pass partly through the urethra, and after a few days later no urine passed by the perineal wound in the urethra. The patient was sitting up on Dec. 1st. On the 18th he left the surgical home untroubled by any urinary symptom, and he is now quite well. The tumour turned out to be of the fibro-adenomatous type, frequently met with in the prostates of the aged, the fibrous elements predominating. It was as hard as scirrhus. About its centre a few drops of pus were found in the middle of a small coagulum, due to a thrombus or irritation of a small prostatic concretion found in this vicinity.

The advantages claimed for this method of operating are:—1. The preliminary external urethrotomy permits of the introduction of the finger into the bladder which, with the finger in the rectum, enables the surgeon to define accurately the shape, density, size, and extent of the prostatic growth in a manner that cannot otherwise be accomplished, except, perhaps, by a suprapubic opening—a much more serious proceeding. 2. The finger can be hooked over the enlarged lateral lobe and the latter pushed well into the ischio-rectal wound, thus to a large extent obviating a deep and dangerous dissection, as in Dittel's operation. 3. With the tumour pushed well into the wound the capsule is easily incised and erased, and the cutting forceps and scissors easily and freely applied to eradicate the whole mass. 4. The finger in the bladder enables the surgeon to feel when the cutting instruments are approaching that viscus, so that he can remove the whole growth, except a thin layer for the support of the mucous membrane of the bladder and prostatic urethra, without opening the latter, thus avoiding infection of the wound and the existence of a permanent fistula. 5. The stout perineal drainage-tube inserted into the urethral wound carries off all the urine and prevents the perineal wound from becoming septic. The drawback to the operation is that, like all other operations proposed for the removal of prostatic growths, it is applicable only to certain forms of the disease. It is not, of course, applicable to cases of enlarged middle lobe projecting into the cavity of the bladder. For such cases McGill's operation is undoubtedly the best. In very fat patients, or when the prostatic tumour is extremely large, it may not be feasible, owing to the fact that the finger may not in such cases be sufficiently long to hook it round the growth.

Operations undertaken for the purpose of inducing atrophy of the prostate.—1. Castration. The apparent analogy between prostatic overgrowths and uterine fibro myomata induced Professor J. W. White of Philadelphia to suggest in 1893 that castration might have the same effect in the former disease that removal of the ovaries has in the latter. It has been demonstrated beyond question that castration in young dogs and other animals prevents development of the prostate, and that in fully-grown animals this operation is almost invariably followed by atrophy of the healthy organ. The same is true of the human male. In addition to the conclusive observations on this point on record I may add that it fell to my lot at one period in India, in the course of my official duties, to examine a large number of eunuchs for medico-legal purposes. Some of these eunuchs had been castrated in infancy; others had voluntarily undergone emasculation through religious fanaticism in early adult life. In one and all of them the prostate was found to be rudimentary.

Castration has now been performed in a considerable number of cases of prostatic enlargement. Unfortunately, the details in a large proportion of the published cases are given in such an imperfect manner that no logical conclusion can be drawn therefrom. There is, however, a sufficiently large number of carefully recorded cases to show that, without accepting the somewhat optimistic views as to results enunciated by Professor White, in a large proportion of patients the subjects of prostatic enlargement that survive the operation castration is followed by shrinkage and atrophy of the gland, with corresponding amelioration in the symptoms, as indicated by diminution in the frequency of micturition; by relief from the burning pain frequently felt at the neck of the bladder; by abatement of the attendant cystitis; by improvement in the character of the urine; by reduction in the quantity of residual urine; by partial or complete return of voluntary micturition; more easy introduction of the catheter; and by general improvement in the patient's health. The atrophy of the enlarged prostate is demonstrable by rectal examination and by the length of the urethra as indicated by the distance the catheter has to be introduced before urine begins to flow.

One of the most remarkable effects of castration is the decided improvement in the symptoms that sets in in many cases a few hours after the operation, particularly in the diminution of pain and in the spontaneous passage of urine when all expulsive power had previously been lost. This is obviously not due to atrophy, for the process of wasting requires time—some weeks in fact—before it displays itself to any marked degree. It must be remembered, however, that the glandular overgrowth is not the only factor, as a rule, contributing to the bulky prostate when the patient comes under observation. There is tumefaction of the organ from congestion and chronic inflammation at the neck of the bladder, and it is to this latter condition that some of the most urgent symptoms are frequently due. Castration has the effect of relieving these urgent symptoms rapidly by diminishing the congestion, thus causing immediate shrinkage of the prostate. How it does so is still a matter of conjecture. Professor White holds that "the removal of the testicles removes this congestion by abolishing the source of the stimulus that excites the function of the prostate." Sometimes the immediate improvement in the symptoms continues and becomes more marked later. At others the immediate benefit disappears after a few days, and marked improvement only sets in after two or three weeks when the atrophy of the gland begins to make progress. In a considerable proportion of cases castration has no effect in inducing atrophy of the enlarged prostate or in ameliorating the symptoms. I believe it will be found that these are mainly cases in which the prostatic overgrowth has assumed the form of fibroid degeneration.

The most serious drawback to castration for enlarged prostate is the high mortality—a mortality of at least 20 per cent.—by which the operation is attended, owing to the advanced age and, in a large proportion of cases, the broken constitutions of the patients. Mental disturbances, sometimes amounting to mania, occasionally follow this operation. These may be of a temporary character, or mania may permanently remain, the patient as a rule succumbing at an early date. It must, however, be remembered that patients with advanced prostatic disease are frequently mentally weak, and that operations of any kind connected with the hypertrophied gland are liable to be followed by insanity. The part played by the anæsthetic in such cases must not be lost sight of. In two cases of mine in which mania supervened on perineal drainage of the bladder for prostatic obstruction I felt inclined to attribute this to the anæsthetic.

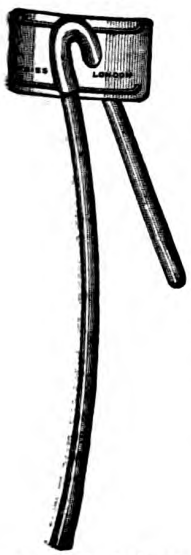
Besides these considerations there is the strong sentimental objection on the part of patients to lose their testicles, even when these organs are no longer of any physiological use. Castration is, indeed, an operation which the surgeon naturally shrinks from suggesting in the early stages of the prostatic disorder or even whilst the patient is enabled by means of the catheter to lead a fairly comfortable and active life. Nor is it likely that the patient would at all readily fall in with such suggestion. No man will consent to have his testicles removed for the purpose of preventing future prostatic troubles whilst anything remains of their physiological function; and even when all virile power is lost patients shrink from emasculation through the consciousness of being thereby unsexed. This may be regarded as false sentiment, seeing that the organs are no longer of any use. Call it what you like, it is only human and has to be reckoned with in practice. A man will only consent as a rule to have his testes removed when less drastic measures have failed and he is driven to it by the agony attendant on the final stages of the disease. When that period is reached castration is in itself an operation attended by a heavy mortality.

These are the considerations that have prevented this

operation from being at all freely resorted to and which have in the last few years induced surgeons to have recourse to vasectomy, which, if not quite so effectual in its results as castration, is practically unattended by danger to life and free from those sentimental objections incident to this latter operation.

2. Vasectomy. This operation consists in division or excision of a portion of the vas deferens. General anæsthesia is, as a rule, advisable; but the operation may be performed with the aid of local anæsthesia, such as the subcutaneous injection of cocaine. The parts having been shaved and rendered aseptic the vas is searched for in the upper part of the scrotum. It is then firmly grasped between the finger and thumb of the left hand and brought as close to the surface as possible. An incision an inch long is made directly over and along the course of the cord, and the dissection is carried down to the vas, which is recognised by its white, glistening appearance. The vas is then grasped by toothed catch forceps, a blunt hook is passed beneath it, and a loop is withdrawn through the wound after separating it from the enveloping fascia. A ligature may be tied round the loop, which is cut off, or separate ligatures may be applied an inch or more apart and the intervening portion may be cut away. The skin wound is closed by one or two sutures. The vas on the other side is similarly dealt with, either at once or after an interval of a few days. This latter course is safer and less liable to be followed by mental disturbances.

FIG. 12.



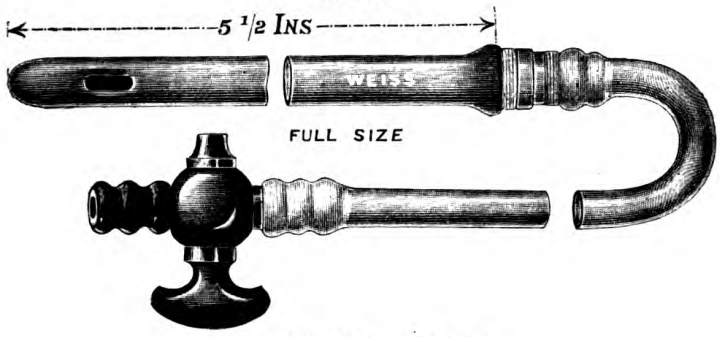
Thompson's drainage apparatus.

I have now performed this operation in a considerable number of cases without any mortality. Indeed, I cannot imagine death resulting from such a comparatively simple operation alone. In none of my cases have I noticed any marked atrophy of the testicles, though in a few instances these organs diminished in size and grew softer. There has been no interference with the sexual power when such remained at the time of the operation beyond the fact, of course, that there was no discharge of semen. In a large proportion of cases there has been decided benefit from the operation, both immediate and remote, similar to those already described as resulting from castration. The atrophy of the prostate progresses much more slowly than after castration and I do not think that it is ever so complete. In a very considerable proportion of the cases there was no permanent benefit from this operation, though, as a rule, there was temporary subsidence of the more urgent symptoms, due, no doubt, to the influence of the operation in allaying the congestion of the prostate. It is probable that the rest in bed, systematic catheterism, and general regime following the operation had considerable influence in ameliorating the condition of the patients.

Vasectomy effectually prevents the recurrent epididymitis and orchitis which are such painful and distressing complications in prostatic patients. This happy result would alone entitle this operation to an important place in surgery. My experience of vasectomy is that it is useless for the purpose of inducing atrophy of the prostate when that organ has assumed the form of fibroid degeneration as recognised by its hard consistence and nodular form by the rectum. It is in those cases in which the enlargement is mainly or solely of the adenomatous type, the gland being felt generally hypertrophied and soft per rectum, that we may expect permanent results from this operation.

I have never seen a single instance in which, after either castration or vasectomy, voluntary micturition was permanently restored when atony of the bladder had advanced to such a degree that the patient was entirely dependent on his catheter. Vasectomy is neither so rapid in its results nor so radical a cure as castration. As, however, vasectomy does not interfere with the sexual power and does not involve emasculation patients consent to its performance at an early stage of the prostatic disease, when it has the best prospect of success, before the degeneration assumes a fibroid character, or irreparable damage is done to the muscles of the bladder.

FIG. 11.



Annandale's drainage apparatus.

Palliative operations.—When in the advanced stages of prostatic enlargement the capacity of the bladder is much diminished in size, all expulsive power is lost, and severe cystitis exists, it may be necessary to draw off the urine by the catheter every hour, or even more frequently, and when, in addition, there are difficulty, pain, and possibly hæmorrhage in the introduction of the instrument, the condition of the patient is indeed a pitiable one. If something further be not done to relieve his condition he rapidly gets worn out from the severe pain and loss of sleep incident to the constantly-repeated catheterisation. Under such circumstances the bladder must be drained, temporarily or permanently as the case may require, through an opening made either in the perineum or above the pubes, thus obviating the introduction of the catheter and giving the bladder complete rest. The method of draining the bladder by the perineum was described in a previous lecture in connexion with stricture of the urethra. Should it be considered advisable to establish permanent drainage by this route this can best be affected by the apparatus designed by Annandale for this purpose (Fig. 11).

To effect drainage of the bladder above the pubes the operation is the same as suprapubic cystotomy for stone. Drainage by this route may be permanently carried out by an apparatus devised by Thompson (Fig. 12), by which a soft rubber catheter is retained in the fistulous opening by means of a silver plate held in position by a belt round the waist and a perineal band. The other end of the catheter passes into a rubber urinal strapped on to the leg.

The considerations that must guide us in our choice between these two operations may be stated thus. The perineal is a much less serious operation than the suprapubic. When, therefore, drainage alone is required and this is to be of a temporary character, and particularly if the patient be very feeble, the former operation should be selected. But if the drainage is to be permanent, if there be suspicion of the presence of calculus, or when, from previous observation by the cystoscope or otherwise, it is known or suspected that an outgrowth of the prostate causing or accentuating the obstruction exists, which is

capable of being removed, suprapubic cystotomy should be employed. By this procedure the bladder at the same time that it is drained can be thoroughly explored and a stone or prostatic outgrowth can be removed. Thick, dense flakes of muco-pus and phosphatic grit, which in cases of this kind frequently adhere to the walls of the bladder, can be scraped off by the finger-nail or scoop and removed by irrigation.

A Clinical Lecture

ON

SOME CASES OF HEAD-INJURY, INCLUDING ONE IN WHICH THERE WAS LESION OF THE OCCIPITAL LOBE.

Delivered at St. Mary's Hospital on Nov. 27th, 1900,

BY HERBERT W. PAGE, M.A., M.C. CANTAB., F.R.C.S. ENG.,

SURGEON TO ST. MARY'S HOSPITAL; EXAMINER IN SURGERY TO THE UNIVERSITY OF OXFORD.

GENTLEMEN,—I hope that you never lose the opportunity of seeing and taking note of the cases of head-injury admitted to this hospital. All of them are likely to be of interest, and many of them will surely present difficult problems for solution. They will provide, moreover, a suitable field for cultivating the faculty of accurate observation, and they will show you how essential is this cultivated faculty for the detection of those minute departures from the normal upon which alone you may have to depend for diagnosis.

There may be comparatively little difficulty in diagnosis or decision as to treatment when you have to do with a scalp wound or a visible fracture beneath it, but when there has been no obvious injury to the scalp or the skull, and the lesion is of parts within the closed cavity of the cranium then begin your difficulties, and the faintest clue must not escape your observation. What are the sorts of things for which you have, then, to look? A hæmatoma in the occipital region, bleeding, or escape of cerebro-spinal fluid from the ear, bleeding from the mouth or nose, subconjunctival hæmorrhage, vomiting of blood, signs of paralysis, however trifling, in the face or limbs, inequality in the pupils, changes in the character of the unconsciousness, convulsive seizures—their nature and duration—any one of these may help you to a solution of the case and enable you to answer the question which the surgeon must always put to himself in cases of head injury, Is there, or is there not, the necessity for operation? From the patient himself small help is to be gained, for in all probability he lies unconscious before you, and you cannot avail yourselves of the Roentgen rays to make a cut-and-dry diagnosis. You have to rely upon your own observation and you will have to bring to bear upon the observations which you make no small amount of thought for their interpretation. Moreover, if you watch these cases without ceasing you will sometimes have the chance of hearing the surgeon think aloud at the bedside, and maybe you will be present at a conference between physician and surgeon when arguments are adduced in favour of, or against, this or that view of the history and the facts observed. A case of this kind was before us only a few days ago. A man, 47 years of age, was brought to the hospital with a letter from the medical man who had been attending him and who wrote that the patient had been suffering from concussion of the brain and that there were now indications of cerebral irritation which led him to think that trephining should be resorted to at the seat of lesion. I am not particularly fond of ready-made diagnoses—they have a tendency to hamper your own judgment; but in this case, perhaps, the diagnosis of another practitioner made us only more careful in our own examination. Well, we failed to find either in the scalp or the cranium any indication of a lesion and it was soon obvious that we had before us something out of the common. The man was not unconscious, he heard and evidently was interested in all that we said, but all that he himself could utter was the word "yes" and, with much greater effort and difficulty, the word "no." We thought we saw some indications of right facial paralysis, but we found no difference in the limbs. Gouty tophi, moreover, were prominent on his ears, his radial artery was tortuous and hard, and the provisional opinion was entertained that the man's condition was not the result of a fall but that some intra-cerebral lesion, either hæmorrhage or thrombosis, was the cause of his supposed accident. We drew off his urine to test for albumin and found it free, the man all the while observing our actions but being unable to speak. We determined to watch him carefully and to take especial note of the convulsive seizures which we were told he had been having for the last three days. There was no change in his condition during the night, and accordingly on the next morning I asked Dr. D. B. Lees to see him with me. He examined him most thoroughly, discovered unquestionable paralysis of the right limbs as well as of the face, and came to the same conclusion as ourselves. At the same time we had the advantage of seeing the patient's wife, from whom we learned that the man had for some months been suffering from gout and had only recently resumed work, and that exactly a week ago he had gone to his work in the evening and within a few minutes was found lying on his back unconscious a few yards from his own door. The unconsciousness was not of long duration and his mental state improved, but he was unable to say more than "yes," and three days before he had begun to have convulsive seizures which had been frequently repeated and in which one-sided phenomena had not been noticed. Dr. Lees agreed with me in thinking that there was no call for an operation and the man has been transferred to his care. This, however, is not the case which I had chosen as the subject of this lecture, and I only refer to it incidentally as one under very recent observation and as providing an example of the sorts of problems which may at any moment be presented to you for solution. The cases to which I now wish to direct your attention have points of interest of their own of a wholly different character from that which we have just considered.

CASE 1.—The first case is that of a lad, 15 years of age, who was admitted on July 6th, 1900. He was travelling on the Underground Railway with his back against the carriage door, and with fatalistic precision a large metal advertisement hoarding fell and struck him on the back of the head. He was brought here in a state of unconsciousness from which he soon rallied, and a lacerated wound of the scalp two and a half inches long was found running along the line of the right lambdoid suture but not reaching quite to the middle line. Brain substance was protruding from the wound. He was said to have been sick several times and to have had a general twitching of the whole body which in the notes is described as being "like shivering." I had him moved at once to the theatre, enlarged the wound, and removed four fragments of bone, two of the sizes of sixpence and a shilling from the outer, and two of three times the size and of irregular outline from the inner table of the skull. These had been driven deeply into the brain substance, from which were extracted pieces of mortar also. The contused and lacerated portions of brain were likewise removed, one suture was passed through the wound in the dura mater, and the scalp wound was brought together with sutures except at one corner which was left open for drainage. The boy was sent back to bed with small hope, I thought, of recovery, but thanks to antisepsis he did as well as possible, and in a few days everything about the wound was perfectly quiet and soundly healed. Mentally he was bright and well. The optic discs were normal.

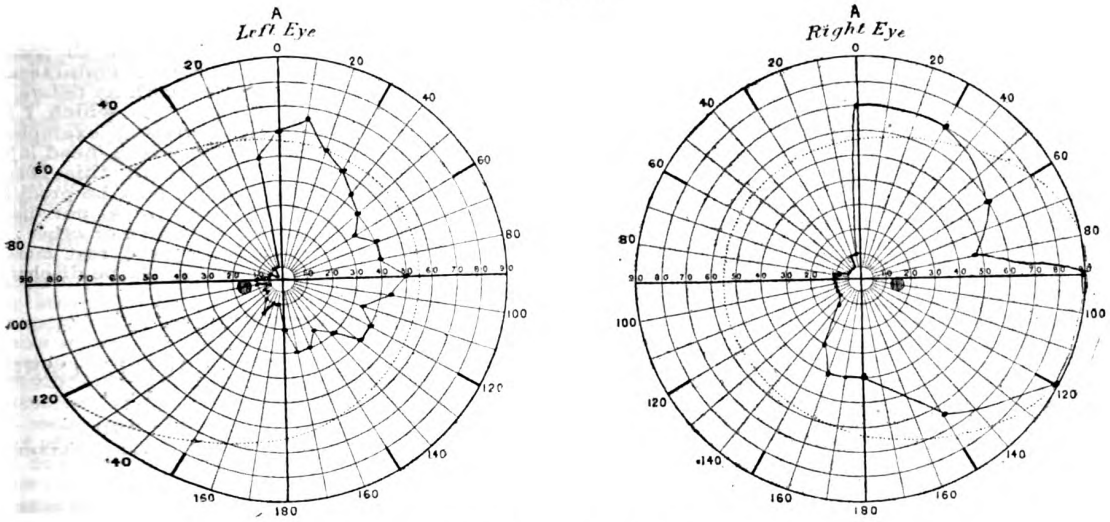
The case, however, had further points of great interest. There had been an injury to the occipital lobe and I thought it would be well to investigate carefully with the perimeter the range of the fields of vision. Some few years ago[1] we had a case of occipital injury in a small child and the belief of everyone who saw her was that, for a time at any rate, the child was blind. The child was too young, however, for special examination, and we had to be content with our belief alone. Here, however, we had a boy, 15 years of age, in whom we hoped that accurate observations might be possible as to the fields of vision, and this Mr. A. G. Wilson very kindly undertook for me. This is not the occasion, nor have I the knowledge adequate, to discuss the

[1] Transactions of the Ophthalmological Society of the United Kingdom, vol. xii.

relationship between vision and the occipital lobes. It will suffice if I read to you a short passage from Swanzy's Monograph on "Eye Diseases and Eye Symptoms in their relation to Organic Diseases of the Brain and Spinal Cord." "While the question," he says, "whether the cortical centre for vision is confined to a part of the calcarine fissure or occupies a more extensive region of the mesial surface of the brain is one of eminent interest, it is, for practical purposes, sufficient to know that this centre is round about the cuneus and the calcarine fissure, that it does not occupy the whole of the occipital lobe, and that it is not on the outer surface of the brain. The most important symptom caused by a destructive lesion of the whole of the cortical visual centre in one hemisphere is complete and absolute loss of function in the corresponding side of each retina and consequently complete and absolute homonymous hemianopsia of the opposite side of each field of vision." I pass Mr. Wilson's perimeter charts round (see Figs. 1 and 2). They speak for themselves and they show that there is blindness in the left side of both fields, implying a loss of function in the right half of each retina. The first one is dated July 9th (three days after the accident), and in succeeding charts of the 14th, the 23rd, and the 31st you will see that the range of the fields is already markedly widening. The fields have been mapped again to-day; and there is a vast improvement, almost if not quite to the normal range, since the patient left the hospital. The boy is here, and you will judge for yourselves that his mental condition is perfectly sound and you will be able to feel the site of the cranial injury. And if you will look at these plates in Macewen's "Atlas of Head Sections" (Plates 29, 31, and 32) you will see that immediately beneath the site of the cranial lesion is the occipital lobe and the calcarine fissure. We cannot, of course, state with the accurate precision of deliberate experiment the site and depth of the cerebral injury. We know that it was superficially extensive, and it may well have been much deeper than the visible appearances, extensive though these were, would have led one to suspect. Bone was driven in and much brain matter was removed. At all events I think we are justified in the conclusion that the temporary limitation in the fields of vision was the result of injury to some parts of the occipital lobe, and from that point of view, if from no other, you will agree with me in regarding the case as one of unusual interest.

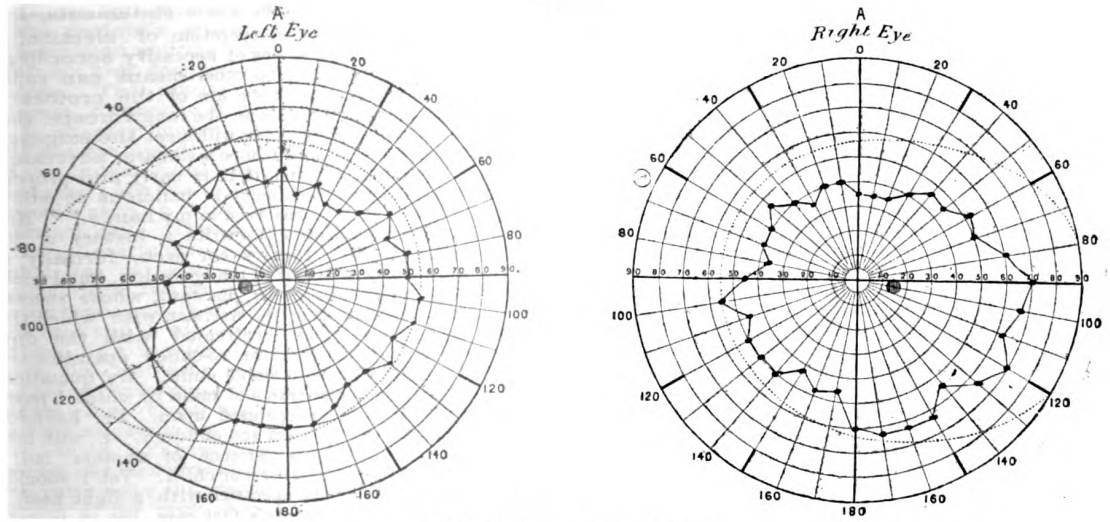
Our next case was of a different and more ordinary kind and I bring it before you because it was one in which a

FIG. 1.



Perimeter charts. July 9th, 1900.

FIG. 2.



Perimeter charts. Nov. 27th 1900.

mistake was made in treatment. Mistakes in practice are commonly instructive. I have never hesitated to tell you of my own, for I feel that if a man will not record his mistakes he had better hold his tongue.

CASE 2.—A boy, aged 14 years, fell from a tree and was admitted in a dazed condition with a large hæmatoma in the right fronto-temporal region. The eyelids were swollen and completely closed. There were no one-sided phenomena, but when I first saw him on the following morning (Oct. 27th, 1900), I thought there was a distinct depression as of fracture beneath the hæmatoma. You know, I dare say, that it is sometimes extremely difficult to say whether there is or is not depression of bone when there is no scalp wound. The scalp tissues may have been severely contused and pulped, and if there be added a definite hæmatoma at the site of the blow the physical state of the parts is very suggestive of a depression of bone. The contrast between the injured tissues and those adjoining is abrupt and is such as to give the impression of a defined edge of bone with a depression which feels exactly like the depression of fractured skull. You have always to take this into account in the examination of a contused scalp without open wound. In this case I felt so confident that there was a depression that as soon as the forehead had been sterilised and the eyebrow shaved an incision was made along the outer half of the brow through the scalp tissues. A large hæmatoma was cleared out and then we found that our supposed fracture was the normal depression of the bone immediately behind the anterior part of the temporal crest. No harm was done, it may even have been well that the hæmatoma was got rid of, and the boy left the hospital on Nov. 6th quite well and with hardly any visible scar.

CASE 3.—The third case is that of a man, aged 29 years, who is still in the hospital. He was admitted on Nov. 9th, 1900, having fallen 60 feet from a ladder and in his flight to earth struck his head against something in the way. He was profoundly unconscious, his sphincters were relaxed, and there was slight bleeding from the right ear. This soon ceased and gave us no further concern and it was not succeeded by escape of cerebro-spinal fluid. There was considerable bruising all over the right side of the head, especially in the sub-occipital region, and it seemed just possible that he might have sustained a fracture of the base. There were no one-sided symptoms suggesting the necessity of operative intervention and our only business was to watch him carefully. Improvement in his mental condition was very slow and it was only after an interval of five days that he seemed able at all to appreciate his surroundings, and then he complained greatly of pain in his head. We also thought that there was some evidence of right facial paralysis, confirmatory, if really present, of our supposition that there might have been a basal fracture, but more recently, when he had still further improved, he was able to tell us that this paralysis was of long-standing, the result of an accident some years before. For days he lay complaining of his head, he could not sleep in consequence, and we deemed it advisable to give him bromide of potassium in the hope that sleep might help to lessen his headache And so it did; he was decidedly better and began to wake up, to take his food better, and to be more alive to things around him. He is now apparently on the road to early recovery, he sits up and reads the paper, but is too talkative and excitable and needs quiet.

We have had in this case an example of what we may call uncomplicated concussion, and yet I would have you remember that after all injuries of the kind the brain itself has almost certainly suffered lesion. In fatal cases you find hæmorrhages, minute or large, in some part of the brain substance, and very commonly there is extravasation of blood into the arachnoid cavity. We are justified therefrom in the conclusion that in those also who recover there has been actual brain lesion. When you get into practice you will often have the questions put to you, what are the prospects of recovery? and what will be the ultimate issue of the case? Very difficult questions indeed you will find them to answer, needing all your tact that you do not commit yourselves to too definite an opinion. They are more likely to be put, and put more often, about cases in which there is prolonged unconsciousness. I do not believe that it is by any means the fact that prolonged unconsciousness is by itself of evil omen. On this very point I have been much interested in the paper by Mr. Tredinnick which you will find in the *British Medical Journal* of Nov. 24th, 1900. "In a case," Mr. Tredinnick writes, "in which I called to my aid the late Sir James Paget in consultation, the unconsciousness had lasted three days and there seemed no means of judging how much longer it might last. He gave it as his opinion that, other things being equal, a certain amount of unconsciousness was good for the patient, as the shaken brain had time more or less to recover, that condition of unconsciousness being for the brain something akin to what a splint would be to an injured limb." I have not looked upon unconsciousness quite in this light myself, but I certainly hold that cases in which unconsciousness has been prolonged are not necessarily those in which there is the worst prognosis. Recently I have seen a man who was unconscious for 14 days after a fall while out hunting, and though there are several abiding local paralyses of special cranial nerves from injury with basal fracture his mental condition shows nothing wrong. This is by no means always so. Concussion of the brain may be followed by all sorts of lasting disturbances, by changes in temper and disposition, by impairment in mental power and physical endurance, by incapacity for the same amount of headwork as before, and even by distinct insanity. In the paper to which I have made reference you will find some interesting examples of the kinds of results which may follow severe head injury. We have seen similar results ourselves in this hospital practice. I do not know how such results may be predicted, but I shall not pursue the subject further now, nor discuss with you the question of treatment, operative or other; but this I would impress upon you: that adequate rest must be given to the brain and that patients must not be discharged too early from the wards.

A SERIES OF 10 SUCCESSFUL CASES OF CÆSAREAN SECTION.[1]

BY W. J. SINCLAIR, M.D. ABERD.,
PROFESSOR OF OBSTETRICS AND GYNÆCOLOGY, OWENS COLLEGE, MANCHESTER.

OVER 50 years ago Dr. Radford of Manchester, in concluding an account of his cases of Cæsarean section in which he lost three mothers and three children out of five cases wrote: "Notwithstanding the unfavourable aggregate results of the Cæsarian section in Great Britain and Ireland I think from my own experience, shown in the above statements, I am justified in advocating it as an operation of election, not merely having recourse to it as one of necessity according to our present obstetric rule when no other means can suffice, but to give it a preference over the use of the crotchet in cases when neither premature labour, the long forceps, these two operations combined, or turning will meet the exigencies of the case. I am a warm, and I hope a sincere, advocate of its adoption and doubt not but if it is early and properly performed and if the after-treatment is judicious it will be even more successful than it has been in my hands."[2] Now it is not my present intention to write a history of the Cæsarean section in this country nor even, formally at least, to attempt a plea in favour of the operation, but I quote with satisfaction the words of Dr. Radford, whose success was only limited, as indicating the aversion with which the experienced accoucheur when confronted with the dire alternative proceeds to perform the so-called operation of craniotomy upon a living and viable child. My quotation will, I hope, hint to you the frame of mind in which I have approached each case to be operated upon. Dr. Radford lost 60 per cent. of both mothers and children. I, with the advantages of the recorded experience of another half-century, have lost neither mother nor child. Yet I should never, I believe, resolve on the operation with a light heart, but constantly, as if it were one's first case, see to it that the operation was "early and properly performed" and that the after-treatment was to the best of my judgment "judicious." It is only, I believe, in this way that the bounds of the indications for the operation will become extended and the results so improved as to banish from practice some of the remaining opprobria of the obstetric art. Without further preface I shall proceed to give the details of my cases, reserving to the end some criticisms and

[1] A paper read at a meeting of the North of England Obstetrical and Gynæcological Society on Nov. 16th, 1900.
[2] Successful Case of Cæsarean Section, with remarks, read at Worcester, August 1st, 1849, by Thomas Radford, M.D., &c.

remarks on indications and technique which the experience that I have obtained suggests.

CASE 1.—The patient, a woman, aged 38 years, X-para, and of German nationality, admitted into the Maternity Hospital on August 29th, 1890, in labour, was confined on the same day and was discharged on Oct. 17th. Her condition during pregnancy had been fair, except for severe "rheumatic" pains. She had suffered from these pains for four years (osteomalacia), but especially during her present pregnancy. Lately she could only move about the house with a sort of painful sliding motion. There had been no complication of pregnancy except the pains mentioned, which were referred chiefly to the pelvis. The patient had had eight children and one miscarriage. In her first confinement delivery had been effected with instruments under chloroform. The child was alive and was living at this time. The puerperium was normal. Her second confinement, which was one of spontaneous labour, was over before her medical attendant arrived. The child lived and was then 15 years of age. There was no "rheumatism" in those days. Spontaneous labour characterised her third confinement also; the child lived for nine years and then died from hydrocephalus. Her fourth labour was a rapid spontaneous one of a living child, who after surviving for 11 months succumbed to "epileptic" fits. There was no "rheumatism." No instruments were used in her fifth labour and the child was still living and aged 10 years. At the sixth confinement, which took place in hospital, instruments were required. The child was living still. There had been no "rheumatism" during pregnancy. The seventh labour also took place in hospital and was effected with instruments under chloroform. The child was living. "Rheumatism" had come on. In her eighth confinement the patient was attended by Dr. Waddell of Rusholme. Chloroform and instruments were said to have been used, but the child came feet first. There was a history of turning having been performed. The child was dead, but was alive at the beginning of the labour. The patient had "rheumatism" all the time; she could hardly walk at all. She was better after the confinement and could walk without sticks. Dr. Waddell warned the patient that if she became pregnant again she must let him know by the sixth month. The next time he heard of her was when he received a summons to attend her when she was in labour at full term. There had also been, as I have said, one abortion. The patient had suckled all her living children. On examination the patient's general appearance was good. She was well nourished and the breasts were large. On palpation the height of the fundus was found to be to the ensiform cartilage. The uterine tumour was very prominent. The conjugate diameter of the true pelvis was about two and a quarter inches. All proportions were lost. The pelvis was crumpled up. The rami of the pubis came so close that the index finger could only be inserted into the arch. Diagnosing the presentation, the head appeared to be unusually high up in the false pelvis. Pains began at 9 A.M. on August 28th. They were strong in character and regular. Artificial interference had to be resorted to, and Cæsarean section was performed. The outlet being contracted (the inguinal canal two and a quarter inches), Porro's operation was performed on the 29th at 4 P.M. Chloroform and ether were used and I was assisted by Dr. Waddell and the house surgeon. An incision was made reaching from two inches above the umbilicus to near the pubes. Bleeding was stopped by the forceps. The peritoneum was carefully opened, and the gravid uterus was brought forward into the wound. An elastic ligature was passed round the neck of the uterus, ready to be tightened when the incision was made. An incision was then made into the anterior wall of the uterus. This came upon the placenta which was cut through. The ligature at the neck of the uterus was tightened and the child was removed, followed by the placenta and membranes. Very little hæmorrhage occurred. The neck of the uterus was compressed by means of the rubber tube by the assistant. Two large pins were passed through the lower portion of the uterus. A wire *serre-nœud* was applied and tightened, but only to restrain hæmorrhage, not to cut. The uterus was then rapidly removed with scissors with but little hæmorrhage. The ovaries and tubes were removed separately, their stumps not being included in the wire. The peritoneum of the stump was secured by sutures to the parietal peritoneum round it and the *serre-nœud* was left on. The abdominal incision was closed in the usual way, leaving the stump projecting from the lower end of the incision which was prevented from sinking back by the pins in the usual way. A drainage-tube was inserted into the peritoneal cavity, reaching into Douglas's space. The wound was dressed with lint and perchloride solution (1 in 2000). The patient bore the operation very well and suffered very little from shock, perhaps because so little blood was lost. The after-treatment was carried out as follows. The temperature at 8 P.M. on the same day was 98°F. and at 10 P.M. it was 99°, and the pulse was 106. Beef-tea and brandy enemata were administered and warm water (a teaspoonful at a time) was given by the mouth. The wound was dressed on the 30th with perchloride solution (1 in 2000), the fluid was drawn off through a drainage-tube, and a catheter was passed every six hours. Suitable nourishment was given. There was no sickness. On Sept. 1st the patient was taking liquid food very well. The urine was passed naturally but the bowels were constipated. Five grains of calomel in separate doses were given and the wound was dressed with perchloride solution (1 in 2000). The patient was sick. On the 3rd the patient took ordinary diet. The wound was poulticed every three hours. On the 4th the vaginal douche was employed and poultices were continued every three hours. There was a great deal of discharge. Several stitches were removed. The stump was sinking. The temperature was 100·4° and the pulse was 80. Ordinary diet was taken and the patient slept well. On the 5th antiseptic poultices were continued every three hours. On the 6th the *serre-nœud* was tightened. The sloughing stump came away without any hæmorrhage or breaking any of the adhesions which had been formed. On the 8th the poultices were discontinued and the wound was dressed with carbolic glycerine (1 in 30). On the 13th the patient looked very well and only rheumatic pains were complained of. On the 22nd she sat up for the first time and said that she felt very well. On the 26th she got out of bed and sat in an easy chair. There was no pain in the abdomen. The rheumatic pains were much less severe and she could move her feet better than she had done for months. On Oct. 14th a small portion of the wound had not healed and there was still some pus. Otherwise the patient was very well On the 17th the wound was still the same. A dressing of red lotion and mercury was employed and the patient was discharged. The child, a male, was born alive and was of full development, measuring 22½ inches in length, and weighing 7 lb. 8 oz. He had improved much when the patient was dismissed from the hospital, but was still having convulsions. He was fed from the bottle.

Note on Case 1.—The nursing notes have been given, perhaps, at too great length. My object is chiefly to call attention to the long and unsatisfactory progress of healing which must be a constant feature of the extra-peritoneal method of dealing with the stump. The obstetric history shows the onset of the symptoms of mollities ossium and its extremely rapid development during the last pregnancy. This disease called for the removal of the tubes and ovaries, and the operation appears to have been moderately successful. I saw the patient at the Southern Hospital about two years after the operation. The child was dead and she had neglected to wear her abdominal belt, so she had an enormous ventral hernia. I have never seen her since, but some inquiries were made about her this summer by the practitioner who was then attending her. I sent him an account of the operation, but I have received no further information as to the progress of the mollities ossium. No milk ever appeared in the urine after operation.

CASE 2.—The patient, aged 23 years, primipara, was admitted to hospital on Nov. 27th, 1890, on which day she was confined, and was not discharged until Jan. 10th, 1891. It was elicited that menstruation had begun at the age of 15 years, that its duration was three days, and that the quantity was small. The period of the last menstruation was from Feb. 1st to 7th. The date of her quickening she did not remember. Her condition during pregnancy had been normal. There were no complications. On examination the patient was found to be a starved-looking deformed dwarf. Her breasts were good. On palpation the fundus was found to reach the ensiform cartilage. The uterine tumour was very prominent. The measurements of the pelvis were as follows: iliac crest, nine inches; iliac spine, seven and a half inches; external conjugate, six and three-quarter inches; true conjugate, three inches; and the transverse diameter of the outlet, two inches. A prognosis of obstruction of labour on account of the deformity of the patient was made. The pains, which began at 3 A.M., were strong in character. Cæsarean section and Porro's operation had to be

resorted to. When the patient came to the hospital on the morning of Nov. 27th the os was found to be of the size of half-a-crown. This dilated rapidly and the head came within reach of the finger but it could not be delivered on account of the contracted outlet, which measured roughly two inches. The patient was greatly deformed, especially about the legs. The urine contained a large amount of albumin. I decided to perform Porro's operation. At 9 P.M. the patient was put under chloroform. An incision was made from above the umbilicus right down through the linea alba two inches above the pubes. The vessels were secured by the forceps. The peritoneum was opened. The gravid uterus was brought out through the incision and an indiarubber ligature was passed round the neck of the uterus. An incision was then made into the anterior wall of the uterus several inches in length and the child was rapidly removed, but the placenta was left. Slight hæmorrhage ensued. As soon as the child was removed the elastic ligature was tightened to control the hæmorrhage. The placenta came away. The *serre nœud* was then applied below the body of the uterus and tightened, and pins were passed through. The peritoneum was then stitched to the uterus, and the uterus was cut away without much bleeding. The abdominal cavity was irrigated with saline solution and a drainage-tube was left in. The stump of the uterus, with *serre-nœud* tightened, was brought forward in the abdominal wound, another pin was passed through the stump, and the peritoneum of the stump was sutured to the parietal peritoneum all round, thus securing the stump in the wound. The wound was dressed with corrosive sublimate solution (1 in 2000) and the stump was dressed with glycerine and carbolic. The patient stood the operation well and did not suffer much from shock. The child, a female, was alive and weighed six pounds. Enemata of beef-tea and brandy were administered. The patient was restless and she was sick twice. The temperature was 99° F. and the pulse was 120. On the 28th the wound was dressed with $HgCl_2$ (1 in 2000) and the stump with carbolic glycerine (1 in 10). The tube was syringed out, removing some clots of blood. The wound was dressed again at 11 P.M. and the tube was removed, the discharge being quite clear. The patient had a good deal of pain. Morphia was administered hypodermically and 34 ounces of urine were drawn off. There was a slight discharge from the vagina. Beef-tea and brandy enemata were administered and warm water was given by the mouth. On the 30th the patient was better; there was less pain, the pulse was 116, and the temperature was 99°. The lower part of the wound and the stump were dressed as above and calomel was administered. There was no milk in the breasts. The urine contained albumin and a trace of sugar. On Dec. 1st the patient was better and the bowels were moved. The wound was dressed and the stump was covered with powder salicylic acid 1 and 2 tannic acid. The pulse was still quick. When the wound was dressed on the 3rd there was a good deal of foul discharge from the stump. The pulse was slower and there was small quantity of sugar and albumin in the urine. The wound was dressed three times on the 4th with spirit lotion. Ordinary diet was taken. On the 5th the *serre-nœud* was removed, with the stump and one pin. On the 6th the wound was dressed three times, the stump and pin were removed, and the cavity was dressed with lint steeped in carbolic lotion. On the 7th the wound was brought together with strapping. A dressing of red lotion was used on the 9th and the wound was healthy and granulating. The patient went home on Jan. 10th quite well. Her general condition was now very good. No milk ever appeared in the breasts, but there was a trace in the urine. The wound healed. The general condition of the child was poor. There was a specific rash and the hair was falling off.

Note to Case 2.—The notes hardly convey a sufficient idea of the deformities of this poor creature. Her extremities were those of a little child, the lower ones being specially ill-developed. She had never been able to walk in the ordinary way, but had acquired such mode of motion as her rudimentary legs permitted. The pelvis was also arrested in development and had in all probability lost its symmetry by efforts at locomotion. The patient and the child are still living. A photograph shown to me this month (November, 1900) shows in the child marked traces of the congenital disease.

CASE 3.—The patient, aged 28 years, II-para, was admitted to hospital on Feb. 26th, 1892. She was confined on the same day and stayed in the hospital until March 31st. In her case menstruation had begun in her seventeenth year. It was of the 28 days type and it lasted for five days, the quantity of the flow being large. She had not menstruated since the last week in May, 1891. Her condition during pregnancy had been very good, no complications arising. There had been one previous pregnancy and delivery at full term. Craniotomy had been performed and the operation had left marked traces on the cervix. On examination of the patient when she was admitted to hospital she was found to present a good general appearance. The breasts were small and the nipples were poor. From the right and left iliac spines to the umbilicus the measurements were the same—viz., eight and a half inches, and from the pubes to the umbilicus the measurement was seven inches. The abdominal walls were firm and the fundus was eight inches above the umbilicus. Iliac crest, 10 inches; iliac spine, nine inches. Vaginal exploration: pelvis—external conjugate, six and three-quarter inches; true conjugate about three and a quarter inches. When the patient was admitted on the evening of Feb. 26th the membranes were said to have ruptured some hours previously, and she was having slight pains. She was put to bed and she remained quiet all night. On the morning of the 27th an enema was given, the vagina was douched with perchloride of mercury, and at 10.30 A.M. the membranes again ruptured, as there was a gush of liquor amnii. The patient was anæsthetised with chloroform and an incision of about seven inches in length was made in the middle line, extending from above the pubes to half way between the umbilicus and the ensiform cartilage. The peritoneal cavity was opened with scissors, and the uterus was drawn bodily out and wrapped in cloths wrung out of hot sterilised water, the peritoneal cavity being filled with warm sponges. An incision was made in the middle line of the uterus and its cavity was opened. The placenta was found to be situated anteriorly, the incision being immediately over it. It was peeled off at once and the child was quickly delivered. An elastic band had previously been passed round the neck of the uterus, and at this stage it was tightened to prevent hæmorrhage. The hæmorrhage was slight and no amnionic fluid was liberated through the abdominal incision, the membranes having been previously ruptured and the fluid allowed to drain away. The uterus quickly contracted and the wound in its walls was carefully sutured with deep silkworm-gut sutures and superficial catgut ones. The uterus was then returned into the pelvis, though the pelvis was too contracted to allow it to be replaced like a normal uterus. The abdominal wound was sutured with deep silk and superficial silkworm-gut sutures, a long Keith's drainage-tube being passed through its upper part, passing behind the uterus into Douglas's space. The lower three-quarters of the wound was dressed with carbolic glycerine and strapped, perchloride of mercury dressing being placed over the tube. At 3 P.M. the patient was very restless and a quarter of a grain of morphia was given. She was sick at 5 P.M. The temperature at 6 P.M. was 98·4° F. She slept for an hour. At 8 P.M. she was again sick; small quantities of hot water were given. A vaginal douche of boric lotion was administered. At 10.30 P.M. one-fifth of a grain of morphia was given. On the 28th the patient complained of having had cramp in the leg all night. She dozed at intervals. One-fifth of a grain of morphia was given at 5 A.M. She slept for an hour and a half afterwards. She had been sick a little twice during the night. An ice-bag had been put on for an hour by order of the house surgeon. The urine was drawn off by catheter—36 ounces since the operation. The temperature at 8 A.M. was 99° and the pulse was 100. On March 1st the bowels acted fairly well. The evening temperature was 99° and the pulse was 104. There was very little milk in the breasts. Urine 54 ounces; it contained no sugar. On the 3rd the breasts were distended and hard, and as the baby could not be got to suck the breast-pump was used and the breasts became much softer. There was sugar in the urine. On the 31st the patient went home in very good condition. The child was a male, living, fully developed, and weighing eight pounds. The infant was fed by bottle as it could not be got to take to the breast and showed at the time of the departure of the patient from the hospital much improvement.

Note to Case 3.—This was the first case of conservative Cæsarean section of the series. The patient was of a different class from those in the two preceding cases. She was a clean, healthy-looking woman without any obvious

deformity, though she was rather under size. The appearance of the head suggested rickets in childhood. The pelvis belonged to the flat rachitic type. She was very anxious to have a living child and I did not think it right to produce sterility by any extension of the operation. It may be noted that after the conservative operation the breasts filled and sugar appeared in the urine. This patient came to see me two years later. She was pregnant between three and four months and talked quite cheerfully of a second operation. A message was sent to me about a month later to say that she had miscarried.

CASE 4. — The patient was a woman, aged 35 years, II-para, who was admitted to hospital on April 2nd, 1892. She was confined on the day of admission and was discharged on May 11th. In the case of this patient menstruation, which began at the age of 14 years, was of the 28 days type and lasted three days; it was small in quantity. She had not menstruated since the last week in June. The patient's condition during pregnancy had been very good, but she had suffered from a troublesome cough. At a previous labour at full term craniotomy had been performed. (It was reported to me indirectly that two medical men were occupied "several hours" with the craniotomy.) The patient was sent to the hospital at the seventh month for examination because of the craniotomy which she had undergone six years previously. The conjugate diameter of the pelvis was from two and a half to two and three-quarter inches, and as induction of premature labour would probably end in perforation now and in future pregnancies, the patient was advised to wait for the full term and then to undergo Cæsarean section and Porro's operation. Physical examination on admission at the end of the term of pregnancy showed the general appearance of the patient to be fairly good. The breasts were large and well-formed and the nipples were good. From the right iliac spine to the umbilicus the measurement was nine inches, and from the left iliac spine it was nine and a half inches; from the pubes to the umbilicus measured seven and a half inches. The abdominal walls were firm. Physical examination of the cervix and orifices revealed the os to be dilated to the size of a florin. The rectum was emptied by an enema; there were large hæmorrhoids. The bladder was emptied by the catheter; there was no albumin in the urine. Pelvis: iliac crest, 10½ inches; iliac spine, nine and a half inches; external conjugate, five and three-quarter inches; true conjugate, two and three-quarter inches or less. A vertex presentation and a first position were diagnosed. Labour had commenced at 2 A.M. on the day of admission to hospital and a Cæsarean section was performed at noon. The patient was put under chloroform, the os being dilated but the membranes were not ruptured, and an incision about seven inches long was made in the middle line of the abdomen. The peritoneal cavity was opened quickly with scissors, the uterus was drawn forwards, secured by elastic tubing, and immediately opened into by a longitudinal incision in its lower half, and the child was quickly delivered. The operation up to this point was completed in a few seconds. The abdomen was then packed with sponges and amputation of the uterus by the intra-peritoneal flap method was proceeded with deliberately, the whole of the body of the uterus being removed. All hæmorrhage was stopped as the operation proceeded and the rubber tubing was still retained round the stump in case of emergency. The uterus having been removed, the stump was methodically sutured, the peritoneum of the flaps being brought accurately into apposition and fine silk and catgut sutures were inserted at very short intervals. The hæmorrhage was easily controlled at all points of the operation. The abdominal cavity was irrigated with saline solution, a Keith's drainage-tube was inserted, and the abdominal incision was closed with deep silk and superficial silkworm gut sutures and dressed with sponges wrung out of perchloride of mercury solution. The patient suffered considerably from shock, but she rallied in the course of the afternoon. At 10 P.M. the temperature was 100·6° F., and the pulse was 130. Nutrient enemata of beef-tea and brandy were administered every three hours and warm water was given frequently by the mouth. On the 3rd it was elicited that the patient had had a very comfortable night. There had been no sickness. She had taken milk and beef-tea in small quantities. The morning temperature was 99°. Urine to the amount of 12 ounces was drawn off by catheter. At 11.30 A.M., the wound was dressed and two ounces of red-coloured fluid were withdrawn. The patient remained very well all day, At 8 P.M. the temperature was 100° and the pulse was 120. There was some suggestion of ether bronchitis. Teaspoonful doses of compound tincture of camphor were given to relieve the chest symptoms. The patient was taking nourishment very well. There was no milk in the breasts. On the 4th it was ascertained that the patient had had a very good night, having slept well. The morning temperature was 93·4° and the pulse was 110. Urine, 47 ounces. A vaginal douche of perchloride of mercury (1 in 4000) was administered twice daily. The discharge was moderate. The wound was dressed at 11 A.M. One and a quarter ounces of red turbid fluid were withdrawn. The temperature at 6 P.M. was 100°. On the 5th the patient was very comfortable. The temperature was 99° and the pulse was 116. Urine, 40 ounces; there was no sugar. The discharge of lochia was free. The wound was dressed at 11.30 A.M. A little clear sanious fluid was drawn off, and the glass tube was removed. On the 7th the bowels acted freely. The patient had had a very good night. By the 20th the wound had quite healed, except a small sinus where the drainage-tube was situated. On May 6th the patient got up wearing an abdominal belt. She felt very well. On the 11th she went home apparently well. The infant was also in very good condition. The patient's condition when discharged from the hospital was very good. There was no milk in the breasts. The child, a female, fully developed, was fed from the bottle.

Note on Case 4.—This case presented a problem which every man must solve according to his conscience and to his views as to his functions as a member of a profession that claims to be guided by ethical considerations—How often are we to perform craniotomy upon a woman whose pelvis will not allow of the passage of a viable child, and to what extent is the problem complicated by a second pregnancy? The special form which the operation took arose from the opinion which I had formed with regard to the tedious healing and other objectional features in the extra-peritoneal treatment of the stump. The absence of milk from the breasts after Porro's operation will be again noted, and there was never any trace of sugar in the urine. I was under the impression that this was the first time in the history of obstetrics that the intra-peritoneal treatment of the stump had been adopted. After some literary research I discovered in an Italian medical journal the record of two cases operated on in the same way by Porro and Mangiagalli at Milan some time before. The after-history of the case has not been obtained, as the patient disappeared from the quarter of the city where she formerly resided.

CASE 5.—The patient was admitted to the Manchester Maternity Hospital on April 10th, 1896. She had been visited by a midwife the same morning, who found her to be in labour and at once sent her to the hospital. She was a primipara, aged 25 years, residing in Ancoats. The following facts were noted on the day of operation. Menstruation began at the age of 17 years and its duration was from four to five days and the quantity was profuse. The date of the last menstruation was the second week in July, 1895. She had quickened in the first week in December and had enjoyed very good health during her pregnancy. There was morning sickness for the first two months, but nothing unusual was observed until the beginning of labour. Abdominal examination showed the fœtus to be lying above the pelvic brim and the head in the right iliac fossa. The uterine tumour was extremely prominent and appeared to rise unusually high towards the thorax. At iliac crests, nine and a half inches; at iliac spines, nine inches; external conjugate, four inches. Vaginal examination showed the diameter of the true conjugate to be about two inches; the membranes were protruding. The external genitals were swollen and darkly congested. The patient had the left hip ankylosed and the left thigh flexed upwards and inwards and pressing upon the abdomen. The right leg was normal. She was extremely deformed owing to the condition of the left leg and the extreme degree of lordosis. She was small in size, had lost one of her eyes, and her teeth were very defective and unhealthy. It was at once obvious that the patient could not be delivered even by embryulcia without much tedious and dangerous manipulation, and abdominal section was resorted to as the best course under the circumstances. The patient was put under chloroform and an incision was made through the abdominal wall reaching from half-way between the umbilicus and xiphoid cartilage to within three inches of the symphisis pubis. The position of the left knee caused much embarrassment from first to last. It was owing to

this special deformity that the wound was made so high up. On opening the peritoneal cavity sponges were introduced to prevent escape of the intestines. The uterus was quickly incised, the membranes were opened, and the child was extracted by the leg. The membranes and placenta were then quickly peeled off. During these manipulations the sides of the abdomen were firmly grasped with both hands by Dr. Scott so as to steady the uterus. When the uterus was dragged forward he promptly applied a strong rubber tube round the isthmus to control the hæmorrhage. In hurriedly extracting the child the peritoneum on the left lower angle of the wound was torn to a slight extent. The uterine wound was closed with deep silk and superficial catgut sutures. The sutures were introduced with Hagedorn needles and were passed completely through the muscle. The rent in the peritoneum was also carefully sutured. The sponges had been so placed as to conceal and protect everything except the uterus itself. On removing the elastic tube there was a rapid oozing of blood; this was finally controlled by additional sutures and manipulating and simulating the uterus into firm contraction. The abdominal wound was closed by deep silk sutures passing through the peritoneum and skin and aponeurosis and superficial silkworm gut only including skin. A Keith's drainage-tube was placed in the lower angle of the wound, being directed to the left, where there was something like a pelvic cavity. The projecting portion of the tube was supported by antiseptic sponges, and a sponge wrung out of corrosive sublimate solution covered by guttapercha tissue completed the essential portion of the dressing. The operation was completed at 1.45 P.M. At 2 P.M. the temperature was 98° F. and the pulse was 116. At 4 P.M. the patient was rather restless; one-eighth grain morphia was given, after which she slept at intervals till 6 P.M.; the temperature was 98·4° and the pulse was 116. Enemata of beef-tea and brandy were given, also sips of hot water by the mouth. There was no sickness. Seven ounces of urine were drawn off by catheter. There was a small amount of albumin. At 10 P.M. the patient was fairly comfortable. The temperature was 100·8°, the pulse was 112, and there was very little hæmorrhage from the vagina. On the 11th, at 10 P.M., the temperature was 101° and the pulse was 140. An icebag was applied to the abdomen. An hour later one-eighth of a grain of morphia was injected. Flatus was passed. The patient was slightly sick once. The wound was dressed at 11 A.M. on the 12th. There was no tenderness or distension. There was no milk in the breasts. Sugar was found in the urine but no albumin. The temperature rose gradually during the day and at 10 P.M. it was 103° and the pulse was 140. A vaginal douche was given during the evening. The lochia were quite sweet. The patient was restless but not in pain. Flatus was passed. On the morning of the 14th the patient felt very well. The temperature was 101·8°, and the pulse was 120. The bowels had acted freely during the night. She was taking plenty of milk. There was no milk in the breasts. A vaginal douche was given. The lochia were quite sweet. The wound was dressed at 9.30 A.M. It looked very well. At 10 P.M. the temperature was 102·8° and the pulse was 120. The patient had a very comfortable day, during a great part of which she slept. There was still a trace of sugar in the urine but no fulness of the breasts. At 2 P.M. on the 15th the temperature was 104°, the pulse was 130, and the respirations were 37. The patient did not complain of anything and seemed to be comfortable enough. At 6 P.M. the temperature was still 104°. Dr. A. W. W. Lea washed out the uterus but found nothing abnormal or offensive. The wound was dressed again and some pus was withdrawn. Two sutures were removed. 10 grains of quinine were given. On the 16th it was ascertained that the patient had slept well during the night and she felt very comfortable in the morning. The temperature had come down gradually during the night and at 8 A.M. it was 101°, the pulse was 112, and the respirations were 30. The cough being a little troublesome a dose of cough-mixture was given. She was taking milk and beef-tea. On the 18th the patient felt very well. The temperature was 98·8° and the pulse was 104. At 6 P.M. the temperature was 101·2°. and the pulse was 102. The cough was again rather troublesome and medicine was prescribed. She was taking milk, beef-tea, and eggs. There was no trace of sugar in the urine. She passed a rather restless night. On the 19th the temperature was 100·6° and the cough was troublesome. At 10.30 A.M. the wound was dressed; it looked unhealthy and not inclined to heal. On the 23rd the patient was going on well and the temperature was normal. The wound, which looked healthy, was strapped and dressed with red lotion. There was no lochia. The douches were continued. On the 29th the patient was very well and the wound looked healthy. A swelling had formed over the sacrum; it looked inflamed, but was not painful. Boric fomentations were applied. The temperature rose in the evening to 100·8° and the swelling over the sacrum was much inflamed. On the 30th the patient was taking full diet, with stout. The evening temperature rose to 103·8°. Dr. T. V. Cunliffe opened the abscess over the sacrum and about an ounce of pus escaped. From this time there was nothing to record except the ordinary facts of convalescence. The involution proceeded only slowly but fairly satisfactorily. The uterus, owing to the narrowness of the brim and other deformities, appeared to remain above the true pelvis, even when the patient was well and ready to go home.

Note on Case 5.—There was at first some ground for fear that cellulitis might occur, owing to the injury to the peritoneum so low down in front of the uterus. The formation of abscess, owing to this cause, was not infrequently recorded as the cause of death in the earlier days of the revival of Cæsarean section. This was the reason for keeping in the drainage-tube for so long a time. It produced a sinus by which an abscess high up under the peritoneum, on the left side to which the injury inclined, might have been reached with comparative facility and safety. In the absence of obstetric symptoms it is probable that the high temperature and pulse were due to some extent to the bronchitis. The uterus was not removed according to Porro's method, or any modification of it, in the belief that the conservative operation was the safest and best. The child was living. It was even vigorous from the first, showing no signs of asphyxia. It was a male, fully developed, and weighed at its birth seven and a quarter pounds. The infant was strong and well when the mother left the hospital, and weighed nine and a quarter pounds. As to the patient's history, the following information was obtained by Dr. Cunliffe, who was the house surgeon during her convalescence. She had been quite healthy until she was five years of age. She then had a fall to which she attributed her condition. She became lame in her left leg after her fall and was admitted as an in-patient to the Ancoats Hospital from which she was discharged as incurable. She did not appear to have been treated for hip-joint disease. Later she was an in-patient in the Clinical Hospital for nine weeks and she said that she was discharged from there as incurable. While she was in this hospital extension appears to have been applied to the left leg for hip-joint disease. At the age of nine years she was admitted to the Crumpsall Workhouse Infirmary where she remained for three years. There two operations were performed upon her, the left hip-joint being excised. At the time she left the workhouse hospital several sinuses still remained about the left hip-joint which continued to discharge for about three years. By that time the hip-joint was flexed to the same extent as at present and her spine was in the same condition of curvature (lordosis). At the end of three years the sinuses had healed up and there had been no discharge from them since. She had had no further trouble with the leg except that arising from the position in which it was ankylosed. The right leg was not abnormal and the patient could walk with the aid of a crutch. The patient went home on June 9th.

CASE 6.—The patient, a married woman, aged 30 years, was admitted to the Southern Hospital. A diagnosis of pregnancy and solid ovarian tumour was made. The patient was admitted to the Maternity Hospital on Dec. 31st, 1899, in the first stage of labour. On examination it was noticed that the abdomen was of a peculiar shape, the uterine tumour being elongated upwards. At the time labour pains were few and weak, although other abdominal pain was present almost continuously. External examination showed that the abdomen was distended by the pregnant uterus but the abdominal ovoid was peculiarly elongated. The fœtal head was felt quite above the pelvic brim and was moveable, and the fœtal heart was distinctly audible high up in the abdomen. Per vaginam the os uteri was found to be displaced upwards and forwards above the pubis and was difficult of access to the examining finger. Only slight and commencing dilatation of the os uteri was found. Bulging into the posterior vaginal wall, commencing about one and a half inches from the vulval orifice, was found a large mass, not fluctuant, but of unequal consistence, and apparently fixed.

This mass was also felt to bulge into the anterior rectal wall. By combined recto-vaginal examination it was readily mapped out in Douglas's space. On examination the head was still above the brim and moveable. The os uteri was still found to be displaced upwards and forwards by the tumour and it was now found to admit two fingers so that the fœtal head could be felt. The tumour itself was still fixed in the same position in Douglas's space. Cæsarean section and ovariotomy were performed on the day of the patient's admission to the hospital, ether being employed. An incision from seven to eight inches long was made in the linea alba. The abdominal cavity was opened and the uterus was exposed. The uterus was withdrawn from the abdomen and protected with warm sponges and towels; an elastic tube was passed round the neck of the uterus and was drawn tight. A large sponge was placed behind the uterus. An incision was then made down the middle line of the anterior uterine wall. Liquor amnii gushed through the wound. The fœtus was promptly extracted through the wound and the umbilical cord was divided. The placenta (which was on the posterior wall of the uterus) and the membranes were peeled off and withdrawn. The shrunken uterus was closed by deep and superficial sutures. The elastic tube was removed and only trifling hæmorrhage occurred. Next the tumour was withdrawn from Douglas's pouch. It was found to be a large fleshy, not fibroid, ovarian tumour with a pedicle. The pedicle was ligatured and the tumour was removed. A Keith's drainage-tube was inserted. The abdominal wound was closed by deep silk sutures and by superficial sutures. The pulse was very good all through the operation. The operation, which was begun at 4 P.M., was completed at 5.30 P.M. At 6.50 P.M. an enema of three ounces of beef-tea and an ounce of brandy was administered. The pulse was 104 and good The patient had to have morphia administered hypodermically several times in doses of one-eighth of a grain to relieve pain which she complained of during the first fortnight and which was caused principally by flatulence. She also had slight headache at times. Vomiting was slight. The temperature was high for the first eight days (from 101·2° to 103·8°). It then gradually became lower, and at the end of two weeks it was normal. The pulse was rather quick for the first 10 days (from 100 to 120), then it fell below 100 and remained steady. Flatus was passed 24 hours after the operation. Three grains of calomel in hourly doses of one grain were given 28 hours after the operation, followed by half a seidlitz powder given six and eight hours after the last dose of calomel, and then again followed in another six hours by a turpentine enema. The bowels were then moved. The bladder was catheterised during the first 27 hours. A trace of sugar appeared in the urine on the day following the operation. There was some hæmorrhage from the vagina in the first 24 hours. The character of the discharge then changed. Vaginal douches of weak carbolic lotion (1 in 100) were administered. On the fifth day after the operation the baby was put to the breast and suckled at once, but would not take it again when put to the breast and so was fed by hand. The mother had not much milk, and there was no trouble with the breasts. A fluid diet was given during the first week. The wound was first dressed 20 hours after the operation. The dressing was done in the usual way, and the drainage-tube was withdrawn. It was dressed again in 48 hours; it looked well. The abdomen was slightly distended. Dressing was done frequently. There was suppuration along the suture track. The wound had to be fomented. The patient made a good recovery, and was discharged eight and a half weeks after the operation.

Note.—This patient was examined in November and the pelvis was found to be normal; there was hardly a trace of tissue changes at the site of the stump of the tumour. The uterus was high and adherent to the anterior parietes as in a case of ventro-fixation.

CASE 7.—The patient was a married woman, aged 27 years, who had had one child (stillborn). She was admitted to the Maternity Hospital on April 4th, 1900, and was advised to wait for full term. She was confined on June 5th and was discharged on July 9th. Menstruation had begun at the age of 17 years. It was of the 28 days type, lasted three days, and was of moderate quantity. The period of the last menstruation was from August 30th to 31st, 1899. Quickening had taken place in January. The patient's condition during pregnancy had been very good. She had been delivered of the stillborn child by forceps on Feb. 7th. The patient had gone to the full term on that occasion. Her health during her present pregnancy had been good. In general appearance she was under-sized, but not deformed. Her breasts were of good shape. The fœtal heart was heard on the right side. Pelvis: iliac crest, nine and a half inches; iliac spine eight inches; external conjugate five and seven-eighths inches. A vertex presentation was diagnosed. Labour occurred on June 5th when Cæsarean section was performed at 11 A.M. The patient was put under ether and a vertical incision was made in the middle line of the abdomen; the uterus was made to bulge through the incision, and an indiarubber loop was thrown round the cervix. The uterus was opened by a vertical incision, the placenta which lay in front was torn through and pushed aside, and the child was removed. The loop was then tightened and the uterus was sewn up by deep silk and superficial catgut sutures, and the abdominal wound by deep silk and superficial silkworm gut sutures. There was no drainage. A dressing of carbolic and glycerine was employed. The membranes were not punctured before the operation. The operation was arranged for and performed in the absence of labour. The child, a male, was alive and was fully developed—length, 20 inches; weight, eight and a half pounds. The condition of the patient on dismissal was good. There was not much milk. The general condition of the child was also good. The breast and the bottle were used in feeding the infant. The umbilicus healed. The patient made a good recovery and the wound was quite healed by the twelfth day. During the day of the operation and on the following day the patient had severe after-pains. These were thought to be induced or increased by the ergotine which had been given. Their severity was modified by morphia. When eight days old the infant weighed six and a half pounds, did not seem very strong, and gained only one pound in weight from the eighth day to the time of the departure of the mother from the hospital.

Note.—When this patient was examined in November it was found that complete involution of the uterus had taken place, but the uterus was high up and adherent in front as after ventrofixation.

CASE 8.—A married woman, aged 31 years, who had had two children and upon whom craniotomy had been performed on each occasion, was admitted to the Southern Hospital on June 10th, 1900. A diagnosis of contracted pelvis and pregnancy was made. The patient having been twice pregnant, but on each occasion craniotomy having been necessary, she, in order to have a living child, gave her consent to Cæsarean section. It was elicited that menstruation, which was of the 28 days type, from four to five days in duration, and moderate in quantity, had been regular and painless. She had last menstruated in the middle of September, 1899. When examined on admission, the patient being in labour, the os was found to be of the size of a florin. The operation of Cæsarean section, which was proceeded with at 4.15 P.M., was completed at 5.15 P.M. A vertical median incision was made in the abdomen and the gravid uterus was made to protrude. An incision was made in the uterus after a loop of indiarubber had been thrown round the cervix. The placenta lay in front; it was rapidly torn away and the child was taken out. The loop was tightened and deep silk and superficial catgut sutures were inserted into the uterus and also in the abdominal incision. There was no drainage. A dressing of carbolic and glycerine was used. Previously to and at the end of the operation one-hundredth of a grain of ergotin was injected hypodermically. A rise of the temperature and quickening of the pulse, owing probably to some suppuration in the suture tracks, followed. The mother could not suckle the child, the breasts not developing at all. Pain was complained of at intervals during the first 48 hours. Morphia in doses of one-eighth of a grain was given hypodermically when necessary. There was no vomiting to speak of until after the patient had had calomel; then she vomited two or three times. During the first nine days after the operation the temperature was high. 12 hours after operation the temperature rose to 102° F. and remained high, rising to 104·2° on the evening of the fifth day. It then gradually fell to normal on the ninth day and remained steady. The pulse remained under 100 during the first 24 hours; then it quickened and was rather rapid for six days (from 100 to 120). Eight days after the operation it fell to below 100 and remained steady. Flatus was passed 41 hours after the operation and after giving calomel. Five grains of calomel in one-grain doses were given 24 hours after the operation, followed in 16 hours by a turpentine enema.

The bowels were then well moved. The bladder was catheterised for the first 12 days. There was no sugar in the urine. There was considerable suppuration along a suture track which had to be poulticed and fomented. There was slight hæmorrhage from the vagina during the first 36 hours. On the fourth day after the operation vaginal douches of boric lotion were given and were continued daily. Fluid diet was ordered as usual. The patient made good recovery and left the hospital nine weeks after operation, she and the child being quite well.

Notes from the Maternity Hospital.—The child, a female, was alive and weighed six and a half pounds. Development was premature. The condition of the child on dismissal was good. The bottle was the medium of nutrition. When the patient was examined on Nov. 10th the cicatrix was 12 centimetres (four and three-quarter inches) long. The uterus was high up and fixed to the abdominal wall. It lay a little to the left. The promonotory could be easily felt with the index finger.

CASE 9.—The patient, a married woman, aged 28 years, who had had two children, was admitted to the Maternity Hospital on August 3rd, 1900, her confinement taking place on August 16th and the date of her discharge being Sept. 22nd. Menstruation had begun at the age of 16 years. She had last menstruated in November, 1899. Quickening had taken place in April. The two previous pregnancies had resulted in delivery at full term; one of the children was stillborn and the other lived 24 hours. Labour in the former case had lasted 38 hours; in the second case, in which the forceps was employed and craniotomy had to be performed, it was of short duration and chloroform was used for three and a half hours. During her present pregnancy the patient had had good health. On examination she was found to be small and delicate—a rachitic dwarf. The nipples were rather flat. The height of the fundus was to the level of the ensiform cartilage. It was vertical and ovoid. The head of the fœtus was fixed in the brim, the back being to the left side of the mother and the limbs to the right side. A uterine bruit was heard. The fœtal heart was heard on the mother's left side. The cervix was dilated and the presentation was a vertex one. An enema and the catheter were used to the rectum and bladder. The pelvis, roughly estimated, was flat rachitic. Cæsarean section was performed on August 16th at 6 P.M., Dr. Lea and Dr. Scott assisting in the work. Ether was administered. The abdomen was opened in the middle line; the uterus was exposed, brought out of the wound, wrapped in hot towels, and incised. The child was removed. The placenta was removed without difficulty. The uterus was then sutured, and having contracted in a most satisfactory fashion was returned to the abdominal cavity, which in turn was sutured. There was no drainage The vagina was packed with CHI_3 gauze for 24 hours. The child, a female, was alive and presented a small incision on the back. She was fully developed and weighed six and three-quarter pounds. The placenta was oval and its weight was one and a half pounds. The membranes were ruptured during operation. The patient was dismissed on Sept. 22nd, five weeks after the operation. There was one stitch abscess, but otherwise the wound healed well. The infant was kept on the breast for the first fortnight; then, as the mother's milk was not enough, she was lastly bottle-fed, and eventually was entirely dependent on the bottle. On the eighth day, as the pulse and temperature indicated some retention of decidua and its infection, Dr. Lea administered an intra-uterine douche. This was followed by a rigor, the temperature rising to 106° F.; after this, save for a temporary rise of temperature on the following evening, the patient made a good and steady recovery in spite of a small stitch abscess which developed near the lower end of the incision.

CASE 10.—The patient, a married woman, aged 26 years, the mother of six children, was admitted to the Southern Hospital on Oct. 4th, 1900. The diagnosis was one of pelvis contracted to a point under possibility of a viable child being born, and the pregnancy was at or near full term. The first child had been delivered dead at eight months. It was thought by the medical attendant to have been dead for some time. The second pregnancy resulted in the delivery of twins and a resort to craniotomy; the third and fourth in delivery at nine months and craniotomy; and the fifth at seven months with craniotomy. The anterior superior iliac spine measured nine and three-quarter inches, the crest 10½ inches, and the external conjugate six and five-eighths inches. Examination per vaginam made during convalescence showed a high degree of antero-posterior contraction. The urine when examined on Oct. 5th had a specific gravity of 1020, was acid, and contained no albumin or sugar. Cæsarean section was commenced under ether on Oct. 6th at 10.30 A.M. and completed at 11.30 A.M. without waiting for the onset of labour pains. The membranes were punctured before operation. An abdominal incision was made as usual, as also was a uterine incision. The indiarubber loop was thrown round the cervix and tightened on the removal of the child. The placenta lay in the fundus uteri and posteriorly. The child when removed breathed immediately. The uterus was sutured with silk and catgut—about 10 of each. In the abdomen silk and silkworm-gut sutures were used. The silk sutures of the uterus were passed to the margin of the endometrium and drawn very tight. With superficial catgut there was no attempt at sero-serous apposition. The wound, after oozing had ceased and the uterus had been kneaded, was rubbed with iodoform. No drainage was needed. The patient loss a considerable amount of blood per vaginam during the next hour and some clots during the afternoon. Ether pneumonia developed in two or three days. Digitalin was administered hypodermically at the end of a week. Aromatic spirits of ammonia and stimulants were given for the pneumonia. After the operation the patient was very restless. There was considerable hæmorrhage. One-fiftieth of a grain of ergotin was injected two hours after operation. Morphia was also given hypodermically and a rectal injection of 20 ounces of saline solution and two ounces of brandy was administered. The hæmorrhage still continued; pressure over the pubes and an icebag were applied. In three hours one-hundredth of a grain of ergotin and one-sixth of a grain of morphia were again injected. The hæmorrhage became less, but did not entirely stop. During the first 48 hours a bloodclot came away at intervals. The hæmorrhage then almost ceased, there still being some blood-stained discharge. Boric douches were given at intervals daily. On the evening of the day of operation bronchial symptoms set in. The patient did not complain of very severe pain after the first two or three hours, and the vomiting was slight. The temperature immediately after the operation was very low—96·8° F. It gradually rose and eight hours after the operation (10 P.M.) it was 101·2° and the pulse was 146. The temperature gradually fell to 98·2° by the following morning, but began to rise again, and in 48 hours after the operation it was 101·6°. It remained high (from 100° to 103·6°) for 18 days, and on the nineteenth day (Oct. 26th, 21 days after the operation) it fell to normal and remained steady. The pulse was rapid (from 146 to 104) from the time of the operation to Oct. 26th, when it fell to below 100. The temperature and pulse rose and fell together during the acute stage of the illness. The respirations were quick and laboured, varying from 28 to 44. In 24 hours after the operation they were 44. There was no pain in the chest. The expectoration was slightly "rusty" on the fourth day after the operation (Oct. 9th). The sputum was only "rusty" once; at other times it was "frothy." The patient did not expectorate freely. There was a slight cough. The wound was dressed for the first time seven days after the operation, when one deep suture was removed. There was some slight suppuration along the suture track. The wound was again dressed in two days, when there was very slight suppuration, which soon cleared away, and the wound healed quickly. The abdomen became distended, but there was no tension or tenderness on touch at any time. Flatus was passed 48 hours after the operation after the administration of five grains of calomel in one-grain doses at intervals of one hour, followed by a turpentine enema. In four hours the bowels were well moved and much flatus was passed. There was no further trouble with the bowels. The bladder was catheterised for 24 hours. There was no sugar in the urine. The patient had no abdominal symptoms. Suitable treatment for the broncho-pneumonia was adopted.

Note.—This patient was examined on Nov. 3rd. The abdominal cicatrix measured five and a quarter inches and the fundus uteri at the lower end of the wound was adherent, anteverted, as after ventrofixation, but otherwise normal; there was no perceptible exudation. The patient was discharged on Nov. 27th looking very well and the child was healthy.

General Remarks.

In addition to the points to which attention has been called in the special note under each individual case there are innumerable details with regard to surgical technique, after-treatment, &c., some "organic details," some less important, that it would be desirable to touch upon if time

permitted. It will be observed by the critical reader when this paper is printed that the nursing notes are given sometimes in considerable detail. This is done in the expectation of drawing criticism as to whether the after-treatment has been what Dr. Radford called "judicious"; of eliciting suggestions from the experienced in the operation with the object, not only of enabling the patient to escape with her life, but of producing favourable post-operation and convalescent stages and diminishing, as far as possible, the dangers and discomforts of the future.

The selection of the time of operation is a matter on which a good deal of difference of opinion appears to exist. In the majority of cases there can be little doubt that in the future, as at present and as in the past, we shall have no choice but to do the best we can with a patient already in labour for a longer or a shorter time. With regard to the time of operation there is a remarkable contrast between the practice of the present time and that of 50 years ago. The Cæsarean section was looked upon then as the last resort and a dire necessity. Then the operation was performed upon a uterus which had become completely exhausted by days and nights of labour; now when the operation is performed it is usually done without delay and the condition of the patient and of the parts to be operated upon are comparatively favourable. It might have been noticed that in two at least of the cases in this series arrangements were made for the operation to be done on a certain day and at a certain hour, just as if they had been cases of abdominal section for tumour. It has been objected that when this is done there may be danger from atony of the uterus. It is astonishing that such an objection should be raised in the face of our experience of induction of premature labour and emptying the uterus for what we believe to be sufficient reason at any stage of pregnancy whatsoever. Another objection, that the os will not be found sufficiently dilated, I believe to be also groundless, whether the patient be primipara or otherwise. The fewer manipulations of the uterus, especially per vaginam, the better, and I have seen no reason to suppose that dilatation of the cervix or the introduction of a cervical drainage-tube in a woman operated on before the onset of labour was at all necessary or even could be otherwise than injurious.

Whether it has been expressly stated or not in the notes, the incision of the uterus has invariably been postponed until the uterus could be drawn forward out of the abdominal wound, and an elastic tube has been always put round so as to be ready to compress the uterine vessels in case of emergency. The uterus has been kept warm by being wrapped in cloths wrung out of sterilised hot water and the bowels have been protected by a suitable packing of sponges. It may be objected that this requires a larger abdominal incision than necessary. When the membranes have ruptured the uterine mass is not so large as one might expect, but there is something in the objection when the membranes are not ruptured. In the last case when the operation was performed before the onset of labour the membranes were ruptured and the waters were drained off by means of a special instrument just before the abdominal incision was made. On the other hand, when the uterus is drawn forwards the operation can be completed with a cleanness and precision hardly attainable otherwise. When the incision of the uterine muscle is rapidly made it is wonderful how little blood is lost even when you come down upon the placenta. In the later cases the elastic tube has been drawn tight, if at all, only after the extraction of the child and the removal of the placenta and membranes. The objection that the use of the elastic ligature causes atony of the uterus is, in my opinion, frivolous. If the deep sutures are inserted as quickly as possible and tied pretty tightly it will usually be found that on relaxing the tube the hæmorrhage is inconsiderable. When the tube is being relaxed the uterus, which has been darkly congested, gradually assumes its natural red or pink colour. If by the time all the sutures are inserted and tied the uterus looks bulky it can usually be made to contract by manipulating it, not with the fingers directly in contact, but acting upon it through a suitable cloth.

As to the size of the wound in the uterus, it should be large enough to permit of the rapid extraction of the fœtus without laceration of the wall of the uterus. I have read and heard that the wound need not be more than four inches in length. As the true conjugate of the pelvis is more than that it may be inferred that a four-inch incision is an estimate, not a measurement as applied to the uterus in Cæsarean section. An added half-inch or more of a clean incision is a small matter compared with laceration of the uterus or asphyxia of the fœtus.

In recent years there has been a good deal of discussion, especially in Germany, on the position at which the incision into the uterus ought to be made, and many cases have been operated upon according to Fritsch's method—that is to say, with a transverse incision through the fundus of the uterus. I must say that to the best of my judgment there is little or nothing to be said in favour of this modification. The drawbacks with regard to the removal of the placenta and membranes are obvious enough, but there are much more important objections. The transverse "Fundusschnitt nach Fritsch" leaves the sutures that have closed the incision into the fundus uteri in such a position that the wound and the suture knots must come in contact with the bowels and omentum; such contact must result in adhesions with possible complications. But there is a worse objection than that; there is a danger that the fundus uteri will adhere to the parietal peritoneum before it has sufficiently undergone involution and cause discomfort by dragging upon the area of adhesion situated high in the abdominal cavity. Further, if the patient has not been subjected to operative proceedings in order to cause sterility the consequences of a future pregnancy must be deplorable. I am decidedly of opinion from experience of ventrofixation that wherever the incision is made the fundus uteri should be left free. When the uterine incision is made in the most obvious position, the middle third in front and in the median line, as involution goes on the uterine wound sinks down and comes in contact with and adheres to the abdominal wound. We then ultimately find the uterus—on examination a month or six weeks, or later, after the operation—just exactly in the position where it remains after a successful ventrofixation operation. If pregnancy occurs the fundus is free to rise and develop just as after ventrofixation in which the fundus is not bound down to the abdominal wall, and so normal pregnancy and parturition remain possible. With a line of firm adhesion between uterus and parietes a subsequent Cæsarean section must be a comparatively easy and safe operation. With increasing experience and confidence it was thought advantageous to abandon drainage.

I do not propose to discuss in full the indications for Cæsarean section and the alternative proceedings, but I should just like, among important points, to call attention to the fact that without having been explicitly condemned by any weighty expression of opinion the operation of symphyseotomy is dying out. Six years ago at the International Congress of Rome it appeared to be the most important and exciting subject under discussion in the Section of Obstetrics. Four years ago at Geneva one heard a good deal about it from Frenchmen and Italians; but now, apart from a few enthusiasts in Paris and in Italy nobody appears to practise it. It is an operation, if justifiable at all, only fit for a carefully arranged operation-room of a lying-in hospital. In this connexion permit me to call attention to a paper recently published in the *Monatsschrift für Geburtshülfe und Gynäkologie*,[3] entitled "Contribution to Symphyseotomy, relating to a Case of Induction of Premature Labour; Symphyseotomy; Perforation," by Dr. Oskar Gross in Breslau. The title is almost a sufficient summary of the case. The mother did not die. Dr. Gross, however, refers to three other cases, not his own, in which perforation had to be resorted to after symphyseotomy. Two of the mothers died and the third was 74 days in the hospital. The results, both as regards mothers and children, immediate and remote, are too problematic for the operation ever to gain a footing in private practice, and if this be true it should be banished from our hospitals. It has undergone several resurrections, which is a pity. I think it was von Winckel who suggested that the sooner it is finally laid in the grave alongside of gastro-elytrotomy the better for humanity.

Concerning the induction of premature labour, it has long appeared to me that the medical profession is dominated by hazy traditional views with regard to its indications and results. Few children are genuinely viable in the case of induction for the higher grades of contraction of the pelvis, although they may be born living. The mortality is appalling even when the best possible care is given to the newly-born infant. Is it evil tradition, or a want of imagination, or a talent for self-deception that makes such obstetrical histories

[3] Band xii., Heft 5, November, 1900.

as that of the patient in Case 10 possible at the end of the nineteenth century? In most cases it would be just as well to frankly resort to craniotomy as to bring on premature labour at 28 or 30 weeks, when the pelvis is so contracted that a genuinely viable child could not pass. From such experience as I have had myself, and from the information obtained by reading numerous statistics and case-contributions from many lands, I believe that it requires very exceptional conditions to make it a justifiable thing to bring on premature labour earlier than in 34 weeks. If you look at the indications for Cæsarean section and compare them with those for the induction of premature labour you cannot fail to be impressed with the shrinking of one and the expansion of the other.

On this subject of premature children Pinard presumes a fuller knowledge than the world possesses when he says: "Nous savons à la fin du XIXe siècle la signification du mot *prématuré*. Nous connaissons l'abîme qui sépare le prématuré de l'enfant à terme, et la différence d'avenir qui est réservée a chacun d'eux." Pinard has done much to add to our knowledge, as distinguished from our impressions, of the fate of premature infants. He refers to the portion of the Paris Maternité where premature infants are taken care of as "établissement modèle où rien n'a été épargné, ni la science, ni le dévouement, ni l'argent"; and what is the result? In 1897, out of 391 infants admitted 292 died within the average time of one month, that is, 70·4 per cent.; and in 1898, out of 482 admitted 343 died within the same average of time, that is, 71 per cent. The relative indications for Cæsarean section and craniotomy on the living mature fœtus would lead me too far afield. The subject is vastly too large for mere *obiter dicta*. One can only ask in half-despair, How long into the twentieth century will the obstetric art continue to act as procuress to invincible ignorance and brutish self-indulgence? Look once more at Case 10: craniotomy on a mature fœtus, craniotomy on twins, craniotomy after induction of premature labour at seven months—that sort of work throws into the shade the practice of an Egyptian midwife.

Manchester.

AN ACCOUNT OF THE EPIDEMIC OUTBREAK OF ARSENICAL POISONING OCCURRING IN BEER-DRINKERS IN THE NORTH OF ENGLAND AND THE MIDLAND COUNTIES IN 1900.[1]

BY ERNEST SEPTIMUS REYNOLDS, M.D., F.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO THE MANCHESTER ROYAL INFIRMARY; VISITING PHYSICIAN TO THE MANCHESTER WORKHOUSE INFIRMARY.

FOR the last 12 months I noticed, both in the medical wards of the Manchester Workhouse Infirmary and in the out-patient department of the Manchester Royal Infirmary, a considerable number of cases presenting unusual skin eruptions of a more or less indefinite character, such as erythema, keratosis, and pigmentation, the last being particularly common among the pauper patients. Some of the pigmented cases were diagnosed as Addison's disease by my assistants, but I could never satisfy myself that this diagnosis was correct. In June, 1900, about six patients presented themselves in one week who were suffering from the typical erythromelalgia or painful red neuralgia of Weir Mitchell, not only the feet but in some cases the hands also being affected; so marked were these cases that in June I gave a clinical lecture on the condition to the students of the Manchester Royal Infirmary. During the last seven months I noticed a remarkable increase in the number of cases of herpes zoster, which appeared to be in epidemic form and during this period I saw probably more cases than I had seen altogether in the past two years.

At the beginning of August quite an extraordinary number of cases of so-called "alcoholic paralysis" were admitted into the workhouse hospital, principally among women. So-called alcoholic peripheral neuritis is a fairly common disease in the Manchester district, very much more common, as I understand, than in London and the south, and perhaps I may be excused for saying that we are specially well acquainted with the affection, for it was principally owing to the work of our physicians, Dr. J. Dreschfeld and the late Dr. J. Ross, that such excellent descriptions were given to the medical world. By it we understand a peripheral neuritis associated with paræsthesiæ and numbness in the hands and feet, paralysis of the arms and legs, cramps of the muscles, and especially great pain on pressure of the muscular masses of the limbs; in addition, there is frequently a dilated left heart with cardiac muscle failure and marked œdema of the trunk and legs and often albuminuria; very rarely, indeed almost never, is there any affection of the cranial nerves. In some cases there is an almost characteristic mental condition with loss of memory for time and place. It may be at once mentioned that the only forms of peripheral neuritis associated with great muscular pressure and pain are the alcoholic, the arsenical, and that form found in beri-beri. By "alcohol paralysis" or neuritis in this paper I mean *so-called* alcoholic paralysis or neuritis.

This great increase in the number of cases of alcoholic neuritis was noted by many observers, some of whom thought that it was due to increased drinking owing to the war fever or to a wrongful expenditure of the money given by the charitable towards the war funds. There was at the beginning of November no longer any doubt that a serious epidemic existed not only in Manchester and Salford but also in neighbouring towns. Now, rightly or wrongly, and this is a matter far too large and important to discuss in this paper, I have for many years doubted whether ethylic alcohol *per se* does cause peripheral neuritis at all, and I have personally felt more confirmed in this opinion each succeeding year. I was therefore in the present epidemic not content with the alcoholic theory but was at once on the look-out for some other possible cause of the neuritis. I could not at first find a satisfactory explanation, but at any rate I confirmed a previous opinion[2] that in this district alcoholic neuritis only occurred among beer-drinkers, not amongst pure spirit-drinkers. Then we noticed at the workhouse that the peculiar skin lesions already mentioned in passing were very often found in the patients who were suffering from neuritis; secondly, a few cases of beautiful herpes zoster were found in the neuritic cases. Thereupon I remembered that arsenic was the only known drug which produced herpes, and so if there was any known drug acting as a poison in the beer it was almost certainly arsenic.

Improbable as this hypothesis at first seemed, yet it was a valid hypothesis, for it was not known to be untrue; it explained all the facts and it was easily capable of proof or disproof. This hypothesis I imagined on Nov. 15th, 1900. On Nov. 17th I obtained some of the beer most commonly partaken of by the sufferers and on Nov. 18th by Reinsch's test I easily obtained a deposit on the copper foil and driving this off in a combustion tube I got well-marked crystals of arsenious oxide, and thus the hypothesis became a fact.

Source of the arsenic.—On speaking to Dr. H. A. G. Brooke about the skin lesions he told me that he was treating a young London hop merchant for similar eruptions, and by his kindness I saw the patient with him and we found that he had undoubtedly got slight arsenical poisoning, although he took very little beer; but he frequently chewed hops, and we concluded that the sulphur with which the hops were treated would be found to be the source of the arsenic. This was soon found, however, not to be the cause of the present epidemic, especially as so little hops are used in making cheap beers. I have, however, been informed that the sulphur is often contaminated with arsenic, and in this way hops on the market often yield a reaction, showing the presence of traces of arsenic, thus accounting for the symptoms in a gentleman constantly tasting them. I communicated my discovery of the arsenic to Professor Dixon Mann on Nov. 19th and on Nov. 20th he examined a different sample of beer and also found arsenic. He informed Professor S. Delépine, who was, unknown to me, also investigating the epidemic at the request of Mr. C. H. Tattersall, the medical officer of health of Salford, and he on Nov. 22nd traced the arsenic to certain sugars used in brewing. These were invert sugar, made by the action of sulphuric acid on cane sugar, and glucose, made by the action of sulphuric acid on various forms of starch. It was easy to see that the sulphuric acid was the common source of the arsenic, and

[1] A paper read before the Royal Medical and Chirurgical Society on Jan. 8th, 1901. An abstract was published in THE LANCET of Jan. 12th.

[2] See Medical Chronicle, June, 1890, p. 189.

on being examined large quantities were found, the original source being the Spanish pyrites from which the sulphuric acid is made and which often contains a very large percentage of arsenic. As it happened the brewing sugars from one firm only were found to be thus contaminated, but as this firm supplies no less than 200 breweries in the north of England and midland counties it will be seen how widespread the epidemic was likely to be.

Quantitative analyses.—By the kindness of Professor Delépine I am able to give some interesting quantitative determinations, the arsenic being estimated as arsenious oxide. Various beers were found to contain from two to over four parts per 1,000,000—that is, from 0·14 to 0·3 grain per gallon. The invert sugar contained 0·25 part per 1000, the glucose 0·8 part per 1000, and the sulphuric acid no less than 1·4 per cent., or four ounces per gallon.

Other sources of arsenic.—From a legal and commercial point of view these results are of the highest importance, but from a scientific point of view it is equally important to know that traces of arsenic may get into beer from other sources. I have already mentioned that it is contained in sulphured hops; it is also found in many samples of malt, getting there either from sulphur or from anthracite coal; it has been found by Dr John Brown of Bacup in the vulcanite tubing used for conveying the beer to the pumps. Again, calcium bi-sulphate and sulphuric acid are used in "fining" the beer, and also, I believe, for cleansing the barrels. Another point worth recording is that many artificial manures are contaminated with arsenic. A possible explanation of the manner in which arsenic may be retained in beer during the various processes and may be of peculiar virulence is that according to the researches of Selmi, Hamberg, Sanger, Saccardo, and others,[3] certain micro-organisms, especially aspergillum glaucum, mucor mucedo, and penicillium brevicaule, seem to have a special tendency to seize hold of any arsenic in their vicinity and to manufacture specially poisonous arsenical products. This has so far been worked out more particularly in connexion with arsenical wall-papers, but, as Dr. R. T. Williamson[4] points out, it is very desirable that further researches on these arsenio-bacteria should be made.

Extent of the epidemic.—Although the epidemic seems to have fallen most heavily on Manchester and Salford and the vicinity, yet many more distant towns in the north of England and the Midlands have been affected—wherever, indeed, the contaminated brewing sugars were used. Thus we hear of outbreaks in Liverpool, Chester (where the cases were associated with so much heart failure and so little pigmentation that they were diagnosed as beri-beri), Warrington, Heywood, Bacup, Preston, Lancaster, Penrith, Ilkley, Leicester, Stourbridge, Lichfield, and Darleston.

Although very many thousands of people have probably been affected, yet it is impossible to say how many and equally impossible to give the number of deaths. For the epidemic had been in existence for nearly six months before anything except alcohol was suspected as the cause; many cases were treated as rheumatism, others as gastritis or diarrhœa, large numbers simply for the skin eruptions, and many merely as cases of chronic alcoholism. Some patients only had slight symptoms and did not have medical attention, while in others the cardiac and hepatic symptoms were the important features. But some idea may be obtained from certain statistics obtained by Dr. J. Niven, medical officer of health of Manchester, and Mr. Tattersall, medical officer of health of Salford. The former in response to a circular received information from 90 practitioners and came to the conclusion that there had been up to the end of November in Manchester only at least 2000 cases. Investigating his death tables, and including deaths certified as due to neuritis, alcoholism, or cirrhosis of the liver for the first 10 months of the years 1897, 1898, 1899, and 1900, he found them to amount to 172, 141, 188, and 253 respectively. In Salford Mr. Tattersall found that in the four months from the end of July to the end of November, 1900, there were 41 cases of death certified as due to neuritis and 25 as due to alcoholism; this total of 66 contrasted with 22 in the first seven months of the year, 39 in the whole of 1899, 31 in 1898, and 27 in 1897.

SYMPTOMATOLOGY.

1. *Complaint of patient.*—In answer to the usual question "What is the matter with you?" the patients have complained of one or more of the following symptoms: pains in the feet, hands, and limbs, burning in the soles of the feet, tingling and "pins and needles" in the fingers and toes, shooting neuralgic pains in the trunk and limbs, difficulty of walking, weakness in the hands and legs, rashes on the body, frontal headache, running of the eyes and nose (cold in the head), bronchitis and hoarseness, a "tired-out" feeling, shortness of breath, swelling of the feet, vomiting, and diarrhœa.

2. *Aspect.*—The aspect of most of the patients is so typical that their cases can generally be diagnosed at sight, not only as they come into the out-patients' room, or lie in bed, but as they walk about the streets of the city. The face is puffy, especially about the eyelids. The eyes are suffused and watery and sometimes running with tears, in some cases the conjunctivæ being œdematous and the vessels so congested that at first sight there appear to be sub-conjunctival hæmorrhages. The colour of the face varies from crimson to a dusky red or even a copper colour. The voice is often "husky," sometimes intensely so, and the walk is that of a patient with very sore feet, so that they seem afraid to put the foot to the ground, or it is somewhat unsteady, or else there is the "high stepping" gait from paralysis of the dorsal flexors of the ankle; in many cases the gait can be diagnosed merely by the noise of the footfall on the ground, the "double-rap" step, as I call it, the heel coming down first, quickly followed by a sudden (not gradual, as in health) descent of the anterior part of the foot and so making the second rap. The patients very frequently are found to be rubbing the fingers together because of the numbness and tingling.

3. *The skin lesions.*—These are very numerous, and almost invariably present in some form or other in greater or less degree. (*a*) Erythromelalgia. This condition, described as "painful red neuralgia of the extremities" by Weir Mitchell, or "acrodynia" by older observers, was one of the commonest lesions. The soles of the feet are crimson, as if stained with red ink, sometimes the whole surface, but more generally only where the surface touches the ground, so that there is left a normal appearance on the inner side at the hollow of the foot and also a transverse line just beyond the distal extremities of the metatarsal bones. The sole, and often the whole foot, is bathed in perspiration which may be stinking (but this is rare). The skin is also puffy even if no true dropsy is present. On the palm the redness may again be uniform but again more frequently it is most marked on the thenar and hypothenar eminences and on the palmar surfaces of the terminal phalanges, the centre of the palm being normal in colour; the whole palm is wet and may be actually pouring with sweat. Both soles and palms are tingling and burning hot and painful, and these signs are greatly intensified by heat, so that the patients cannot sleep unless the feet are exposed to the air outside the bedclothes.[5] The pressure of the bedclothes cannot be borne and the surfaces are exquisitely painful on pressure, so that, as I have said, the gait is affected, and the patients cannot use the hands even if no paralysis is present. This erythema does not become pigmented, but passes on to keratosis. (*b*) Keratosis. This condition seems to be a somewhat late manifestation and is at any rate very frequently secondary to the erythema and hyperidrosis of the palms and of the soles. I have watched it develop on the hands and feet and can thus speak with some certainty. It may take several forms, it may be in a few isolated scaly masses, either thin or very heaped up in marked prominences, and in this way previous corns on the feet or patches of tylosis on the soles or palms become extraordinarily prominent. In some cases the keratomatous patches appear on the dorsum of the hand between the webs of the fingers and on the knuckles. In more marked cases either the whole palm or sole is thickly covered with large white or dirty grey scales which are constantly being shed into the bedclothes; or the centre of the palm and inner side of the sole may be merely erythematous and dry but not covered by scales. Sometimes the keratosis extends up to the ankles and on to the wrists, but the scales are now not thick but more like a branny desquamation. The palms and soles may both be affected, but the soles are almost always the worst, and sometimes are affected alone. Moreover, in cases where

[3] Allbutt's System of Medicine, vol. ii., p. 989.
[4] Brit. Med. Jour., Dec. 1st, 1900.

[5] Rarely the patient says his feet are very cold, but on examination they are found to be hot.

there is no pigmentation keratosis may be present and forms a most valuable aid in the diagnosis of a case which might otherwise appear to be merely one of alcoholic paralysis. The process is very slow (many weeks) in its development and seems to be if untreated extremely chronic. (*c*) Erythemata. These are very varied in character and are often accompanied by great irritation. There is sometimes a scarlatiniform eruption on the upper part of the chest spreading to the neck and face, sometimes on the forearms and rest of the body. At other times, and perhaps most frequently, it is a morbilliform rash on the trunk and limbs running into scarlatiniform patches; often it is a more distinctly papular erythema and not infrequently there is an acute urticaria. In some the change is so intense that there is a vesicular eruption in which the lesions may vary in size from that of a pin's head to large bullæ several inches in diameter; those which I have seen have been almost always on the limbs. In one or two cases the appearance has been that of a true pemphigus, and when the contents have been shed circular marks have remained, like very superficial scars. These vesicular eruptions are probably a late form of rash, even coming on six weeks after the last glass of beer has been taken. The erythematous papules sometimes become larger, run together, and are covered with scabs in patches, so that there may be after many weeks an appearance somewhat like lupus or even of superficial syphilitic ulcerations. (*d*) Pigmentation. This is generally not present in light-complexioned patients or merely amounts to a darkening of pre-existing freckles. In darker people it is practically always present in greater or less degree, but in many is so diffuse that it may entirely escape notice. In most of the cases it follows (after many weeks) the erythematous blush, which gradually turns from red to copper-colour, then to bronze, and in severe cases almost to black, so that many of the patients resemble mulattoes. Even if it is thus almost universal it does not affect the palms and soles nor, as a rule, does it touch old scars in which the deeper layers of the skin have been destroyed, but round the edge of the scar it is much intensified, the scar thus seeming to be of an especially white character. Round the neck, in the armpits, round the nipples, on the abdomen, round the genitals, and on the buttocks, where there has been pressure, as round the waist or under the garters, it is much deeper in tint and, indeed, resembles the pigmentation of Addison's disease; but I have not seen any pigmentation of the mucous membrane of the mouth. Although well seen on the face of many patients yet on the whole it is more marked on the trunk. Frequently the pigmentation shows well-marked lighter spots like "rain-drops." In other cases the pigmentation is seen on close examination to be punctiform. In others it is in isolated spots varying in size from a pinhead to patches equal in size to the palm of the hand, clear light-coloured skin intervening, and often these isolated patches run together to form a continuous pigmentation. Not only is the colour like that of a mulatto but the texture of the skin takes on the same beautifully soft velvety feel to the touch, quite different from that of normal English skin. In many cases after many weeks a branny desquamation of the pigmented skin takes place, so that by friction one can rub off the pigmentation as it were and leave healthy skin underneath. Having watched numbers of these cases for weeks I am convinced that there is a distinct sequence of events — namely, an erythema followed by pigmentation and then a desquamation—so that the pigment is really a part of the general altered nutrition of the skin and is not due to a deposit of metallic arsenic in the skin as was once thought; this view does not necessarily exclude the idea that the drug may be partly eliminated by the skin. (*e*) Herpes zoster. This was the tell-tale eruption which, as I have said, gave me the key to the puzzle. When it occurred without any other very definite symptoms, then I considered that I was dealing with epidemic specific herpes, but when I found other signs of arsenic poisoning present there could be no doubt that it was also arsenical in origin. Since the discovery of the arsenic practically every case of herpes zoster has been found to have other unmistakeable signs of arsenic poisoning in greater or less degree. I have seen rarely herpes of the fifth cranial nerve, a few cases of the ascending branches of the cervical plexus, several of the other cervical nerves, many of the dorsal nerves, and one of the first lumbar nerve. In no case has the herpes been bilateral and generally only one nerve-root was affected, but in two cases I have seen two succeeding nerve-roots affected; I have seen no herpes below the elbow or below the knee. From the great number of cases seen in this district there is to my mind no longer any doubt that arsenic causes herpes by a direct action on the posterior spinal ganglion, just as much as it acts directly on the motor and sensory nerve fibres; this seems to me to be a much more probable view than that put forward by Dr. H. Head that arsenic is only a remote cause of herpes, inasmuch as it renders a person more liable to attack by specific herpes. In fact, how many of the epidemics of so-called specific herpes (such as that described by Dr. Head as occurring in 1897 during the long drought that lasted from July to November) have not really been due to arsenical poisoning? From actual therapeutical observation I have seen a few cases of herpes develop when I have been giving small doses of arsenic in which the only other sign of arsenical poisoning was lacrymation and a silvery tongue. I am indeed convinced that it may come on with quite small doses. The herpetic eruptions have always been preceded and accompanied by very severe neuralgic pains along the course of the nerve or nerves affected. And I may here state that I have had many cases with severe neuralgic pains in the arms or round one side of the trunk which I expected would be followed by herpes, but none appeared. (*f*) Nails. In many cases the nails are affected. After the patients have stopped taking the beer for some weeks the best appearances are seen, for then there is a transverse white ridge across the nail; proximal to this the nail is normal, but distal to it the nail is whiter, cracked, thin, and towards the tip almost papery and much flattened. In some cases there have been a series of parallel transverse ridges on the nails almost suggesting a series of week-end "drinking bouts." These deformed nails of course break easily. (*g*) Loss of hair. One or two women have told me that they have lost the hair during the attack, but this has certainly not been a marked feature.

4. *Nervous system.*—(*a*) Sensory affections have been present in practically all the cases. In the mildest they have merely consisted of paræsthesia and tinglings and burning and pricking sensations in the fingers and toes; in others these conditions have been combined with numbness of the hands and feet and sometimes of the legs below the knees. I have not seen a case of *total* loss of sensation, although the numbness has been very pronounced. Part of the apparent loss of power in the hands and feet has been due to this partial loss of sensation. In one case there was very marked, but not total, anæsthesia of the whole left fifth cranial nerve, but its motor fibres were unaffected. This is the only instance in which I have seen any affection, either sensory or motor, of the cranial nerves. Neuralgia of the arms or trunk, either followed or not by herpes, I have already alluded to. Finally, and of the greatest diagnostic importance, there was in a large number of the cases (but only if there was some loss of power) tenderness on pressure of the muscular masses of the legs and arms; sometimes deep pressure was required, but in other cases light pressure produced most exquisite pain and caused the patients to scream out and to exhibit a very typical facial expression of terror or in less marked cases merely a screwing up of the facial muscles in a "grin of pain." (*b*) Motor. These symptoms were similar to those ordinarily found in so-called alcoholic neuritis. They were present in greater or less degree in about 70 per cent. of the cases. In the slighter cases there was only slight loss of grip and slight affection of the gait, and there was then no appreciable atrophy of the muscles. In more marked cases there was a total paralysis of the affected muscles with very marked atrophy. The small muscles of the hands, especially the interossei, the muscles of the forearms, especially the extensors, and in severe cases all the muscles of the arm, were involved. If the muscles of the upper arm were not affected then also the supinator longus escaped to a large extent, as in lead-poisoning. In the early stages in the feet there was loss of power with some slight irritation of the extensors of the toes, so that the great toe was well extended and "cocked-up." In this stage the knee-jerk was always either present or exaggerated, but there was never any ankle clonus. But soon the muscles became paralysed and atrophied, first the interossei and the anterior tibial and peroneal groups, so that the toes were flexed and the whole foot dropped at the ankle into a position of talipes equino-varus. The calf muscles were next affected and at about the

same time those of the thigh, accompanied, of course, with rapid wasting and loss of the knee-jerks. The superficial reflexes were normal or exaggerated. Even in this stage the muscles on the front of the trunk were weak, so that the patients could not raise themselves in bed, and in some advanced cases there was well-marked diaphragmatic paralysis, with laboured breathing and a markedly ineffective power to cough. In one case with comparatively slight loss of power in the limbs the diaphragm was entirely paralysed. It goes without saying that in the most advanced cases the patients lay in bed totally helpless. There was no paralysis of the sphincters except in the most marked cases, in which some of the incontinence was possibly due to the mental condition, and the intercostal muscles were never paralysed. I never saw any paralysis of the cranial nerves in any case. The walk I have already described as a "stepping" gait, but many of the patients were distinctly incoördinate in their movements, and swayed slightly on standing with the eyes closed, but to my mind there was never any real resemblance to the ataxic walk of a case of tabes. (*c*) Mental. In many of the cases of advanced paralysis there was the peculiar mental condition commonly found in alcoholic paralysis. This has been called "confusional insanity," but it is more accurately described as a total loss of memory of time and then of place. There is a loss of initiation of ideas, but any suggestion, however absurd, is at once accepted. Thus a totally paralysed patient who has been in bed for weeks when asked if he has not been for a walk this morning will say that he has and will tell you with much circumstance where he has been; and when asked about yesterday will perhaps say with a little prompting that he has been to the seaside. If asked when he came into hospital, he will always turn towards the nurse at the other side of the bed and say: "Let me see, I think it was yesterday [or some other near date], wasn't it, nurse?" But, taking only the paralysed cases, I am inclined to think that the amount of mental confusion has been distinctly less than I should have expected from as many cases of ordinary alcoholic paralysis, which rather leads me to think that arsenic has not much effect on the cerebral cortex.

5. *Circulatory system.*—In the majority of the patients there has been some heart failure. In the milder cases this has been limited to dyspnœa on slight exertion, palpitations, post-sternal or epigastric pain, and a low tension pulse. In more marked cases the heart muscle has shown great failure and the left side of the heart has been dilated, the apex-beat has been in or outside the nipple line, and the left border not infrequently outside the nipple line; the beat was sometimes diffuse. On auscultation the heart sounds have approached the fœtal "tic-tac" type, the second sound being accentuated and the diastole shortened to the length of the systole; in some cases there was a soft systolic mitral murmur. Exertion has increased the pulse-rate considerably and there has sometimes been a rapid heart without accompanying fever. So great has been the cardiac muscle failure that several patients have fainted on getting up for the first time, and undoubtedly the principal cause of death has been cardiac failure; this has been noticed as the chief cause of death in arsenical poisoning by Brouardel in the Havre epidemic in 1888 (homicidal poisoning). Œdema affecting merely the feet only or almost the whole body has been observed in 25 per cent. of the cases. On the trunk it may manifest itself by the skin taking and retaining the impression of the stethescope over the heart. There is often a well-marked pad of œdema over the sacrum, and the genitals are sometimes enormously œdematous. The legs may have such a tense, hard œdema that it is difficult to make an impression on them with the finger. There has been a fair amount of ascites, but no great amount of pericardial or pleuritic effusion, certainly not so much as is said to occur in beri-beri. In the Chester cases there seems to have been an unusual amount of heart failure and œdema. Both from the cases which I have seen and from those reported in other epidemics I have no doubt that arsenic will seriously affect the heart muscle quite independently of alcohol.

6. *Respiration.*—Just as the skin is irritated by the arsenic so the respiratory mucous membrane seems to be in its whole course. There are in the early stage running from the eyes and nose, congestion of the fauces, a very marked congestion and thickening of the vocal cords producing the typical hoarse or husky voice (not due to any paralysis, as I have proved by laryngoscopic examination), and very pronounced bronchitis. Not infrequently there has been hæmoptysis in patients who were certainly not suffering from phthisis. Not a few of my cases have shown signs of phthisis with fairly rapid breaking down of the lung tissue. And it is interesting to note at the present time, when arsenic is being largely recommended for the treatment of phthisis, that some of our patients with signs of rapid phthisis give a history of apparently previous phthisis which has seemed to be in abeyance but has been lighted up in a virulent form by drinking the arsenicated beer.

7. *Digestive system.*—In many of the cases digestive troubles were the first signs; although loss of appetite was present in severe gastric cases, on the contrary in mild cases the appetite seems to have been definitely increased. There was, of course, no blue line on the gums in any case, but in a few the gums were red and softened. The tongue in the early stage had a typical thin white silvery coat, as if if it had been brushed over with lunar caustic. In later severe stages it was brown, but as a rule it was moist. Vomiting, quite sudden and very copious, was a marked feature, sometimes occurring immediately after each pint of beer taken or immediately after a meal. Many patients came to the hospital suffering from sensory disturbances and said that they were spirit-drinkers only, but on inquiry I found that they had been beer-drinkers a few weeks previously, but had voluntarily stopped the beer because it was not "agreeing" with them, as they were so sick, and this occurred before it was known that arsenic was present in the beer. Some patients complained of diarrhœa, and as these cases occurred in October and November I was quite at a loss to explain the cause, especially as they had not as yet shown other signs of arsenical poisoning, although they were obviously alcoholics. In a few cases there has been passing of blood by the stool, but whether this was secondary to congestion of the liver or to ulceration of the intestine I cannot say. At the work house hospital during the last six months we have had quite an unusual number of cases of cirrhosis of the liver (this organ being much enlarged, hard, and tender), with great ascites. Dr. A. C. Sturrock, the resident medical officer at the Manchester Royal Infirmary, has noticed the same increase there.[6] Brouardel has also mentioned cirrhosis of the liver in pure cases of arsenical poisoning, and I cannot doubt but that arsenic will set up an interstitial hepatitis.

8. *Urine.*—In a considerable number of cases there has been a trace of albumin in the urine, but quite possibly this has been secondary to the cardiac failure. In many cases this disappears later, so that I have no evidence to prove that there has been renal cirrhosis. We have not found any sugar in the urine. But a more interesting and important fact is the presence of arsenic in the urine of those patients who had been drinking quite recently. Professor Dixon Mann on Nov. 26th obtained the arsenical reactions quite easily from only six ounces of urine passed by a woman who had been recently drinking, and its presence in the urine has also been detected by Dr. J. H. Abram and Dr. Nathan Raw[7] and others. There is no doubt also that the arsenic is excreted by the milk, as I was informed by a mother who was affected that her suckling child vomited after each meal (which had never been the case with any of her previous children). Mr. G. S. Taylor of Salford[8] reports also a clear case of the suckling infant being affected.

9. *Temperature.*—In the early stages in several cases the temperature has been raised, varying from 101° or 102° F. in the morning to 102° or 103° in the evening, the other signs of early arsenical poisoning being fairly acute. In some cases this pyrexia has disappeared after a week or 10 days in bed; in other cases it has lasted two or three weeks, and in a few it has continued until death. Thus in the early stages in previous epidemics there has been some excuse for the cases having been diagnosed as influenza or even as typhoid fever.

Summary of symptoms and order of sequence.—From the above account it is clear that arsenic is almost certainly a cumulative poison although some authors say that it is not so. Moreover, it is a poison which affects both the skin and the respiratory and digestive mucous membranes, the nerve trunks, both sensory and motor, and the muscles (including the heart muscle), and the liver. As regards the sequence of the symptoms Brouardel[9] has clearly laid them down and I can confirm his statements. The sequence is: (1)

[6] Brit. Med. Jour., Dec. 22nd, 1900, p. 1815.
[7] Ibid., Dec. 8th, p. 1683.
[8] Medical Press and Circular, Dec. 5th, 1900, p. 585.
[9] Annales d'Hygiène, 1889, p. 479.

digestive symptoms; (2) laryngeal catarrh, bronchitis, and acute skin symptoms; (3) disturbances of sensibility; and (4) motor paralysis (and pigmentation and keratosis). Widal in the Hyères epidemic gives the following actual dates in one of his cases: Feb. 8th, gastric disturbance and diarrhœa; March 4th, acute cutaneous eruptions, spasmodic cough, running of the eyes and nose; March 31st, sensory disturbances in the limbs, then some days later paresis of the upper and lower limbs. Health was only restored after one year.

The course of the disease is a slow one. The gastric, coryzal, and laryngo-bronchial symptoms pass off first, then the acute skin lesions, which pass on to the chronic skin lesions, which, I think, will be found to last many months. The erythromelalgia and sensory symptoms are still almost as marked as ever in patients whom we have had under observation for four or five months, and judging from analogy of so-called alcoholic paralysis the motor disturbances will last for from 18 months to two years before they entirely disappear.

Mode of death.—In most of the cases this seems to be from cardiac failure, either quite suddenly or gradually. Some patients have died from paralysis of the diaphragm with secondary broncho-pneumonia, and in one case at least phthisis contributed to the fatal issue.

Classification of cases.—The cases may be roughly divided into groups: (1) those with all symptoms fairly well marked; (2) those with skin lesions principally; (3) those with cardiac and hepatic lesions principally; and (4) those with paralytic lesions principally. A careful examination into the history and present state of any case will, however, reveal some concurrent symptoms quite characteristic of arsenical poisoning. Thus in a fair-complexioned woman who had no apparent symptoms but paralysis, which could not be diagnosed from so-called alcoholic paralysis, there was in addition keratosis of the soles of the feet.

Diagnosis.—Once the possibility of arsenic poisoning is recognised there is no difficulty whatever in diagnosis. There is no other disease which will produce the same grouping of symptoms. In the early stages it is possible to mistake the condition for measles or scarlet fever and in the later for Addison's disease, and in some cases it will be difficult in the present state of our knowledge to say that certain cases cannot be entirely explained by chronic alcoholism. Only a thorough consideration of the history and full examination of the patient will prevent mistakes being made. In beri-beri there are said to be but few skin lesions.

Treatment.—I shall say little on this point, for having entirely stopped the intake of the poison, the treatment becomes merely a matter of dealing with symptoms. One point, however, is of great importance; on account of the alarming heart symptoms from muscle failure no depressing drugs should be given. We must thus avoid potassium iodide, sodium salicylate, antipyrin, exalgin, phenacetin, &c. Small doses of digitalis, with some other diuretic, tonic doses of strychnine, gastric sedatives, carbonate of ammonia, and senega, will probably be required. For the pains we must have recourse to small doses of morphia. The burning sensation in the hands and feet is much relieved by spirit lotion. The other skin lesions must be dealt with *secundum artem*, but this is a subject which I would rather leave to the dermatologists. The treatment of the neuritis does not differ from that which is already well known.

Previous epidemics.—Space will not allow me to do more than mention some previous epidemics of arsenic poisoning. Graves[10] mentions that he had witnessed part of the curious "*épidémie de Paris*" which occurred in 1828, in which there were peripheral neuritis, acrodynia, and many other of the symptoms which I have above described. There can be little doubt that this was an epidemic of arsenic poisoning. I have been unable to find Chomel's original paper, but Barthélemy[11] says, also, that it appears to have been due to arsenic and that in four or five months it caused the deaths of 40,000 persons on the western bank of the Seine near Paris. Brouardel and Pouchet[12] call attention to an epidemic affecting nearly 500 persons at Hyères in 1888 and reported by Widal, in which white arsenic had by mistake been put into wine instead of gypsum; also an epidemic at Havre in 1888 in which 15 persons were affected from arsenic put intentionally into food. Brouardel also alludes in passing to an epidemic, which he had investigated, from arsenic in bread,[13] and I have seen a statement made, but cannot confirm it, that in 1884 in the Département du Midi (France) some wine sold was found to contain a considerable quantity of arsenic which was derived from the sulphuric acid with which the old wine barrels had been repeatedly washed, whereas the same wine which had been stored in new barrels was quite free from the poison.

Pathological anatomy.—This subject I do not intend to allude to, as it is being investigated by others. In the few cases in which I have been present at the post-mortem examinations the only prominent signs were the interstitial hepatitis and the dilated flabby heart.

Personal statistics.—During the three months—October, November, and December, 1900—I had charge at the Manchester Workhouse Infirmary of 343 patients suffering from arsenical poisoning, 192 being men and 151 women. During November and December at the Manchester Royal Infirmary (out-patient department) I treated 157 patients similarly affected, 99 being men and 58 women. This gives a total of 500 cases, 291 being men and 209 women. This preponderance of men over women is contrary to what I supposed at first was the case, but the symptoms were on the whole more pronounced in women. The deaths were 13, five of men and eight of women. The ages varied from 26 years to 70 years and either beer or porter was invariably taken as a beverage, alone or together with spirits. The amount taken has varied from as small a quantity as two pints (possibly only one and a half pints) to 16 pints a day. The herpes was more common in men, for out of a total of 21 cases seen in three months 16 were in men. The heart symptoms with anasarca and the liver enlargement and cirrhosis with ascites were also more common in men. But the gastro-intestinal, the coryzal, and the sensory and motor disturbances were more common in women and as a rule were shown in a much more marked degree. In 80 cases in which specially careful notes were taken seven women out of 37 had marked loss of memory of time and place, but only one man out of 43 was thus affected. Also of these 37 women 27 were suffering from loss of power, 10 of them to such a degree that movement of the much atrophied limbs was practically impossible. Of the 43 men 17 had loss of power, the loss being of a total character (in the limbs) in six cases. In all the cases of paralysis the legs were more affected than were the arms.

Manchester.

CASES OF ARSENICAL PERIPHERAL NEURITIS.

BY ROBERT J. M. BUCHANAN, M.D. VICT., M.R.C.P. LOND.,

HONORARY PHYSICIAN TO THE STANLEY HOSPITAL, LIVERPOOL; ASSISTANT HONORARY PHYSICIAN TO THE LIVERPOOL HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST; ASSISTANT LECTURER ON TOXICOLOGY AT UNIVERSITY COLLEGE, LIVERPOOL.

FOR the past four months I have been interested in the number of persons presenting themselves at the out-patient rooms of the Stanley Hospital on my days of attendance who exhibited symptoms of neuritis in various ways. In two cases, both those of women, there were large outbreaks of herpes zoster of the intercostal variety and in another case, that of a man, there was herpes zoster distributed from the buttock down the posterior surface of the thigh; in the cases of the females the skin of the abdomen and back was of a pale umber colour. Other patients complained particularly of peculiar pains in the hands and feet and on examination their cases were diagnosed as cases of peripheral neuritis probably due to alcohol. In the case of two patients particularly who confessed to having taken small quantities of beer, and that only at meal times, the possibility of lead as a cause was considered, but there were no special diagnostic symptoms to support it, and yet it was difficult to understand how the alcohol alone could have been the sole cause of, and could have produced, such marked symptoms, for none confessed to spirit-drinking. There is no doubt now, however, that these cases were the outcome of arsenic in the beer and I thought it would be of interest to describe briefly some of the more characteristic features noted.

CASE 1.—A married woman, aged 42 years, came complaining of pains and numbness in the hands and feet with

difficulty of walking. She stated that she never had any previous illness. For some months she had noticed a difficulty in going upstairs. Since about the middle of August she had suffered from intermittent attacks of coryza and gradually increasing numbness in the fingers which interfered with her work as a cigarette-maker. She had suffered more or less with diarrhœa for two years, but since August she had had attacks of vomiting and griping pains with six or eight loose motions daily. Pain in the soles of the feet preceded by cramps in the calves and thighs came on at about the same time that the fingers were affected; the legs, feet, and hands were swollen and the finger left an impression on the swollen legs; the face also was œdematous. The patient's senses of taste and smell were almost completely lost. Her complexion had gradually become "pasty and sallow" and her skin very dry and "mealy." Her condition on examination was as follows. The face was pale and sallow and was rather puffy, with a mask-like appearance; the cheeks were pigmented, with clear spots as if the bronze colour had been washed off; and the eyelids were very dark. There was bronzing, extending down the neck and becoming darker near the axillæ; the nipples were very dark and the abdomen had the same umber colour; and the skin was desquamating like fine bran. The skin of the hands was peeling and dry on the palms, with the palmar lines looking like streaks of flour, and the nails were brittle, while the tissues around them were swollen and shiny. The patient stated that her hands felt tense and that her skin felt like a tightly-fitting glove. The fingers were anæsthetic, which was most marked in the thumb and gradually lessened to the little finger, which was very slightly affected—the anæsthesia had travelled from the thumb to the index and middle fingers in sequence, then after a short interval to the ring finger—and there was fine tremor of the hands. The anæsthesia did not extend over the wrists nor were the arms tender on pressure. On holding a cup, if she exercised sufficient pressure to retain it, it caused pain in the fingers. There was marked loss of contour of the legs and slight œdema; the skin was dry and scaly, but there was no pigmentation. The feet dropped and the arches were almost obliterated as in flat-foot; the skin was blue and shiny, there was acute tenderness of the soles and, on pressure, over the nerves of the leg, with general hyperæsthesia. The knee reflexes and the plantar reflexes were absent. There was not much wasting and paresis was not very marked. She could raise herself on her toes and flex the ankle against slight resistance. There were no ataxia and no headache and the memory was good. The tongue was white, flabby, and silvery in appearance. There was no pain after food and the appetite was good. She was suffering from diarrhœa with straining and soreness, which she stated was as if she had "piles." The motions were fluid and frothy; they contained no blood but considerable quantities of mucus. There was occasional vomiting. The urine did not contain albumin or sugar. The pulse was 102, small and irregular. The heart-sounds were weak, with the first sound reduplicated occasionally and like the second in character. She stated that she had taken only three glasses of beer per diem and that it was always procured from the same public-house. Two weeks later (on Dec. 2nd, 1900), when she had given up taking the beer, all diarrhœa, vomiting, and coryza had ceased and the œdema had almost disappeared. On the 4th the urine was examined for arsenic but with a negative result. Only a small quantity, however, was obtainable for the purpose.

CASE 2.—The patient was the husband of the woman in Case 1. He had had similar gastro-intestinal symptoms with coryza while taking the beer, and had become pigmented, but exhibited no symptoms of neuritis. These symptoms disappeared on his discontinuing the beer.

CASE 3.—The patient was a female, aged 63 years. The symptoms commenced early in August, 1900, but for a month previous the woman had noticed weakness of the legs on going upstairs. She had had attacks of vomiting and diarrhœa with colic—six motions during the day and four during the night; the motions were jelly-like but contained no blood. There was marked watery discharge from the eyes and nose but no sore-throat. The skin became dry and scaly and for six weeks she had had pains in the feet with increasing difficulty in walking and some staggering, and two weeks later the pains came on in the hands. The pains were always worse at night while in bed. While attending as an out-patient for three weeks her symptoms increased, and on Nov. 15th she was admitted into the hospital, her condition on admission being briefly as follows. The patient was a fairly well-nourished woman. Her hair was turning grey; her skin was dry, scaly, and very pigmented, especially over the abdomen, the chest, and the back, in parts subjected to pressure, and in the axillæ and inner sides of the thighs, fading towards the legs, the arms, and the face. Pigmented patches were present on the temples and at the roots of the hair on the forehead. The skin was desquamating freely all over, especially on the back and on the sides, also on the calves. On the dorsum of the hands and feet the skin was glossy and bluish, while on the palms and soles it was dry and peeling; the nails were brittle. The heart sounds were weak and "fœtal" in character, the first and second sounds being of similar character. The pulse was 108, small, and collapsing. The nervous symptoms consisted of pain in the intercostal regions with a marked girdle pain at the lower part of the thorax. There was acute tenderness over the nerves of the legs on pressing the calves, causing her to scream; and the same tenderness was present in the soles of the feet; it was not present in the arms but was marked in the fingers. There were anæsthesia and excessive sweating of the fingers, which followed upon shooting pains. She was unable to feed herself, there being great loss of power in the hands, and she was prevented from standing by loss of power in the legs. There was well-marked hyperæsthesia of the skin of the feet. The knee plantar reflexes were absent and there were flail ankles. The abdominal reflexes were absent. The pupils reacted to accommodation and light. The wasting of the arms and the legs was considerable. The patient slept badly and her memory was slightly impaired for recent events, but there was no delirium or incoherence of speech. The appetite was poor; there was no pain after food, but the patient had diarrhœa. The tongue was shiny and white. The urine did not contain albumin or sugar. The patient confessed to drinking only two glasses of beer daily but no spirits. She had obtained her beer from the same public-house for seven months, previously to which she had not experienced any symptoms.

CASE 4.—The patient was a female, aged 60 years. She came to the hospital complaining of weakness of the legs and the hands for the previous three months. Six months before she had had sneezing and watery discharge from the eyes and nose which lasted for six weeks, and there had since been intermittent attacks. There was no vomiting or diarrhœa. Pains in the soles of the feet and in the ankles had developed and increased during three months. There were suffusion and redness of the conjunctivæ, and the skin of the face was darkly pigmented, the pigmentation increasing over the neck, the chest, the back, the armpits, the shoulders, the buttocks, the thighs, and the abdomen, fading towards the arms, the hands, the legs, and the feet; in places it appeared as if it were splashed with rain. In the most pigmented parts the skin was almost like that of a negress. Exfoliation was very marked, the exfoliated epidermis appearing white in contrast to the general bronzing. The finger nails were brittle and the nails of the great toes were loose. The hair had fallen off very considerably. Pains with numbness and anæsthesia were noted in the fingers. The patient had severe pain in the feet; she stated that she could not bear the weight of the bed-clothes upon them. The soles were exquisitely tender, also the nerves of the leg, pressure eliciting screams. The skin of the feet was hyperæsthetic up to the ankles. The knee and plantar reflexes were absent; there were no ataxic symptoms. The digestive system had not been affected. The tongue was smooth and silvery looking. The heart sounds were altered so that the first sound was short and sharp but feeble. The pulse was 102 and almost imperceptible. The woman acknowledged having taken only "two gills" (= three glasses) of beer daily, and she had always obtained it from the same place.

CASE 5.—The patient was a female who complained of hoarseness and cough which had been coming on for three months, also the rapid enlargement of a previously small goitre, with pain and numbness of the hands and feet. She first noticed that a short walk made her tired and that her legs felt "heavy." The hoarseness and bronchitis had gradually developed, with a constant sense of irritation in the throat. For a month she had a discharge from the eyes and the nose like clear water. Her skin had become very brown, but it was clearing; it had "come off," she said, "like oatmeal and in flakes," especially from the hands and feet. When the patient was seen by me on Dec. 7th the

pigmentation was very marked and the face was dusky, the general distribution of the pigmentation being as in Case 4. On the back was a patch of erythema about eight by ten inches, sharply defined, and exhibiting dermographia on friction. When her initials were scratched upon it they stood up as wheals in bold relief. The pigmentation faded towards the hands and feet. The tongue was silvery and exfoliating. The patient had suffered from purging with tenesmus and smarting, but had passed no blood by the bowel. She attributed this to the beer she had taken, which always gave her a burning feeling in the chest and stomach. There was great tenderness on pressure over the nerves of the legs and also on the soles of the feet, with hyperæsthesia. The knee and plantar reflexes were absent; there was no ataxia, no wasting, and no marked paresis. Examination of the chest revealed general bronchitis. The heart sounds were rather feeble, but there were no murmurs. Exertion caused dyspnœa. The pulse was 96, small, soft, and regular. Menstruation had increased, and the last period had been excessive. The thyroid gland was much enlarged, more on the right side than on the left. There was no pulsation or murmur, the increase in size having been recent. The gland had never caused her any trouble before but had become a source of much discomfort. The patient took "sixpenny" beer with her meals, three glasses per diem.

CASE 6.—A man, aged 47 years, complained that his right hand felt "asleep," with a feeling of "pins and needles." For a week his legs had become weak and numb and as if he were "standing on ice." He could not work owing to the weakness of the legs. He had had coryza for two weeks and he had also had looseness of the bowels for the same time. The skin was dry and scaly and the nipples were very brown. There was a pigmented macular eruption on both sides of the body, the buttocks, and the thighs; on the latter it was in long streaks following scratching. There was a separate patch on the right buttock two and a half inches square, and one on the abdomen. The face was dusky and expressionless. The man had difficulty in picking up pins with his right hand as he could not feel them. There was a feeling of "pins and needles" in both legs, with slight superficial anæsthesia, but great pain on pressure over the calves and the soles of his feet. The knee and plantar reflexes were absent, but the paresis was not pronounced. There was slight ataxic gait on walking with the eyes shut. There were no mental symptoms. The pulse was 86. The heart sounds were normal. The tongue was pale and silvery, but there was no gastric disturbance. The patient confessed to taking two glasses of beer at night but no stout, and he said that he always got his beer from the same public-house.

CASE 7.—A man was admitted into the hospital complaining of loss of sensation in the arms and legs; he said that on standing or walking he felt as if a round ball were under the sole of each foot. He had been in the habit of drinking beer but not to excess, and he very seldom drank spirits. His illness commenced in October, 1900, with "cold in the head"; he had also vomiting and diarrhœa. On walking he experienced pain in the calf muscles; weakness of the legs below the knees developed, and later the hands and arms became affected. He had gradually lost weight. The pigmentation of the skin was not very deep in colour with the exception of the axillæ, the groins, and the nipples. The skin was dry and desquamating in fine powdery scales; the skin of the hands and feet was shiny and bluish. The finger-nails had each a well-marked transverse ridge, indicating in period of growth the approximate date of the initial trophic disturbance. There were no special symptoms in the alimentary system. The pulse was 72 and of low tension. The heart sounds were feeble and distant but there was no bruit. There was slight general bronchitis with cough. The patient slept fairly well; there were no headache and no mental disturbance. He walked with difficulty and with a "stepping" gait. There was marked hyperæsthesia of the hands and the forearms, also of the feet and the legs. Pressure over the nerves in the calves caused great pain. The soles of the feet were very tender on pressure. There was marked wasting of the muscles of the arms and legs, with loss of contour in the limbs, loss of power, and "drop foot." The patellar reflexes were absent and the plantar reflexes were diminished. There was no œdema. The specific gravity of the urine was 1005; it was acid but there was no albumin or sugar.

The above series of cases exhibited a characteristic train of symptoms; other cases, however, in which there was sufficient reason to attribute the symptoms to the same cause were less typical and varied in severity. The following may be taken as examples.

CASE 8.—A woman, after three years' abstinence from liquor, took it in excess for two weeks. Violent vomiting, diarrhœa, and depression ensued. The tongue was furred and the mouth and gums were ulcerated and painful. The pulse was 120 and was very feeble. The heart sounds were "fœtal" in character. There were pains in the hands and calves, with great tenderness on pressure. The knee and plantar reflexes were exaggerated.

CASE 9.—The patient was a man who had always been in the habit of drinking from four to five pints of beer daily but who had never experienced any ill effects until the end of November, 1900, when he suffered from severe gastro-intestinal symptoms and coldness and feelings of numbness in the hands and legs. When seen in the out-patients' room he was extremely depressed, with pronounced tremor, and was continually hawking up mucus from the throat. There was great pain on pressing over the nerves of the legs. The face was puffy and the skin was dry. There was no pigmentation. The patellar reflexes were exaggerated and the plantar reflexes were diminished. The pulse was 160, very small. The heart sounds were "fœtal" in character. The face was puffy.

CASE 10.—The patient, a man, suffered from œdema of the legs with pain on pressure over the nerves. The knee-reflexes were diminished. There was also anæmia. There was no pigmentation. Slight gastro-intestinal symptoms were present. The pulse was irregular, small, and frequent. The heart sounds were feeble.

CASE 11.—The patient was a man, showing pigmentation and fine desquamation round the waist, in the armpits, in the groins, and in the nipples. There were hoarseness and bronchitis but no gastro-intestinal disturbance. Pain and tenderness of the sole of the right foot were also present. The right knee reflex was absent and the left knee reflex was normal.

CASES 12 and 13.—These cases were those of two females who showed herpes zoster of the right side of the trunk with intercostal neuralgic pain. They had also pains in the hands and in the feet, with pigmentation of the trunk.

CASE 14.—This was the case of a man who had herpes zoster of the right buttock extending down the thigh to the ham.

CASE 15.—This was the case of a man who suffered severe urticaria, with pains in the arms and the legs. The urticaria disappeared with the discontinuance of the beer. Several days later on taking beer a fresh outbreak was precipitated.

CASE 16.—The patient was a female who had had coryza for two weeks. There were four loose motions daily. She suffered from great thirst. There were numbness in the hands and occasionally in the legs and pigmentation of the sides of the trunk. The skin was dry and desquamating particularly over a large area on the left side of the trunk. The tongue was clean, fissured, and glistening. The pulse was 80, regular and small. There was a systolic mitral murmur.

In the majority of instances I was able to locate the establishments at which the patients had procured their beer and I felt justified in notifying without delay the names and addresses of the patients and the establishments to the medical officer of health of the city.

Liverpool.

THE ROENTGEN RAYS AND THE DIAGNOSIS OF URINARY CALCULI.

BY C. MANSELL MOULLIN, M.D. OXON., F.R.C.S. ENG.,
SURGEON AND LECTURER ON SURGERY AT THE LONDON HOSPITAL.

WITHIN the last few weeks I have had under my care a series of cases which illustrate in an unusual degree the value of the Roentgen rays in the diagnosis of renal, ureteral, and vesical calculi. Thanks to the improvements in technique which have been effected in the course of the last two years the results obtained by Roentgen photographs may, so far as calculi are concerned, be regarded as final and conclusive for all ordinary cases. Unless there is some unusual difficulty, such as an abnormally stout abdomen

or, as in one of my cases, an extreme lumbo-dorsal curvature, displacing and burying the kidney, the Roentgen rays can be relied upon to give definite and accurate information not only as to the existence of a calculus but as to its size, its exact position, and, what is even more important, whether there are other calculi present either in the same or in some other part of the urinary tract. There need, therefore, be no fear lest, as has happened before now, an operation should be performed by some mischance upon the wrong organ or on the wrong side. The best results, of course, are obtained with calculi composed of oxalate of lime, as these absorb the rays to a much greater extent than others, but even concretions of phosphate of lime can be made to throw a distinct shadow, unless they are so minute as to be of no practical importance, and a negative result can be relied upon as much as a positive one. If no calculus is shown after a second examination, repeated under varying conditions, it may be taken as certain that there is no calculus there. Out of eight cases radiographed by Lennard of Philadelphia in which the result was negative on subsequent examination nothing was found in seven cases. In the eighth case it was known at the time that the technique was faulty and that no reliance could be placed upon the result.

In many instances Roentgen photography is the only method by which the presence of a fixed calculus can be ascertained. I have published elsewhere[1] a case in which I removed a small cortical calculus from the right kidney of a patient who had had his appendix removed nine months before by another surgeon without deriving the least relief. As usual in the case of a cortical calculus there were none of the characteristic symptoms of stone in the kidney. The stone was fixed and never came into contact with the orifice of the ureter, so that there was no renal colic, or hæmaturia, or retraction of the testis, but merely constant aching pain referred to the right iliac fossa and made worse by every attempt at exertion and attended by a feeling of sickness. A single exposure revealed the cause, and with the removal of the calculus the pain ceased entirely.

Even when there is no doubt as to the existence of a calculus the assistance derived from this method of investigation is scarcely less valuable, especially in the case of renal calculi. In another patient of mine, who was under the care of Dr. J. G. Ogle of Reigate, the clinical symptoms were so definite that the diagnosis of stone in the kidney was practically certain; but nothing could be ascertained about the size of the calculus, or its position in the kidney, or whether there might not be more than one, hidden away, perhaps, in one of the calices. A single examination with the Roentgen rays proved beyond all question that there was only one stone and that it was fixed in the cortex and at the lower end of a particularly low-placed kidney. In consequence of this I was able to extract it through the smallest possible incision and with a minimum amount of manipulation. Had it not been for the skiagram it would have been necessary to have exposed the whole kidney, and to have palpated it thoroughly, perhaps even to have dragged it out of the wound on to the loin, first to find the stone, and then to make sure that there was no second stone present.

When the stone has left the kidney and is passing down the ureter the condition of the patient, as a rule, is such that quiet examination is not possible. In one case, however, in which the course of the stone was temporarily arrested just below the brim of the pelvis, I obtained definite information both as to its presence and its exact locality. Fortunately, under active purgation, it soon began to move on again, and it was ultimately passed without any operative measures being required. Had it remained fixed where it was the information would have been of the utmost value in determining the exact situation for the incision. In two cases of suspected ureteral calculus under my care, in which the evidence given by the Roentgen rays was negative, the subsequent course of events proved that it was perfectly correct. In one case it was thought that there might be a calculus impacted in the lower end of the ureter, as, in addition to other symptoms, there was a peculiar prominence of the mucous membrane of the bladder just behind the orifice of the ureter and visible through the cystoscope, but on examination nothing was found. In the other case the patient, who had suffered from repeated attacks of colic down the left side of the abdomen for some months before and in whom the left kidney was unusually sensitive to pressure, died suddenly from acute intestinal strangulation a fortnight after the skiagram had been taken, and the kidney and ureter were found at the post-mortem examination to be perfectly free.

Under ordinary circumstances the Roentgen rays are not required in cases of vesical calculus. The diagnosis is easily made with a sound, aided, especially in children, by the introduction of the finger into the rectum; but there are many cases of enlargement of the prostate in which this method fails completely. Stone in the bladder is much more common in association with enlargement of the prostate than is usually believed, and is very often overlooked. Sometimes the stone lies in a definite sacculus and sometimes it is merely caught behind the prostate and held by it against the trigone. In either case, however, it never comes into contact with the neck of the bladder, it never gives rise to the characteristic symptoms, and it is exceedingly easy to miss with a sound. There may be pain, it is true, but it is not the characteristic sharp cutting pain of stone in the bladder, felt at the end of the penis, and coming on as the last few drops of urine are expelled. Micturition may be unduly frequent, but the frequency is either more marked during the night than during the day or else is so extreme that such exercise as the patient can take makes little or no difference. Blood is often present in the urine, but more often than not it precedes or accompanies the flow instead of following it; and though the stream of urine often stops before the bladder is emptied, it is not arrested with that abruptness and sudden pain which characterise the dropping of a calculus into the neck of the bladder and the sudden spasmodic contraction of all the muscles around it. It often happens in these cases that the only indication of the presence of a calculus is the obstinate persistence of cystitis which resists all ordinary measures; and I am strongly of opinion, from the frequency with which I have found calculi present, that whenever this persistence is a prominent feature in association with enlargement of the prostate a special examination for calculus should be made without further delay. The severity of an attack of cystitis depends upon the kind and number of the septic organisms that get in and upon the conditions which favour their growth. Persistence in the face of treatment thoroughly carried out points to some lasting cause which is much more often a calculus than is usually imagined.

Now in many of these cases the prostate is so large, partly from over-growth and partly from long-continued congestion, that the ordinary methods of examination are useless. A sound, if it can be introduced and rotated in the bladder, cannot be made to explore the post-prostatic pouch or any sacculi that have been formed without an amount of manipulation that is often most injurious. A cystoscope frequently cannot be introduced at all, and owing to the length of the prostatic urethra the finger in the rectum cannot lend the least assistance. Hence it is that under these circumstances even large calculi may be overlooked. But with the Roentgen rays there is no difficulty. Without putting the patient under an anæsthetic, without passing anything up the urethra, without causing pain or even inconvenience, without the least risk of hæmaturia, or septic cystitis, or shock, an examination with the Roentgen rays will prove within the course of a few minutes whether a calculus is present or not, no matter what may be the size or shape of the prostate or how distorted the bladder. Not only can the presence of a calculus be shown, but very valuable information can be obtained as to the size, number, locality, and sometimes even composition. The shadow of the calculus is projected on to the plate with that of the coccyx. (The patient must lie upon his back, as the prone position is only suitable for moveable calculi.) Making allowance for the fact that the coccyx is somewhat nearer to the plate a fairly approximate idea can be obtained as to the size of two of the diameters of the calculus. No direct information, of course, can be obtained as to that of the third. The stone may be disc-shaped and not thicker than a penny—not an unusual shape in cases of this kind—or it may be spherical. In either case the area of the shadow would be the same. If, however, the shadow on the negative is distinctly lighter than that of the coccyx, in spite of the latter being nearer the plate, it can only mean either that the stone is of considerable thickness, or that it is composed of oxalate of lime, or both. The actual size, however, and the hardness of the calculus are not so material under these conditions as is its position. The material point is that a calculus is present, either behind the prostate or in a sacculus, that it cannot be reached by a sound, and that therefore it is no use trying

[1] Archives of the Roentgen Ray, November, 1899.

to crush it by means of a lithotrite introduced through the urethra.

There is no need for any exceptional apparatus. It is usually recommended that the tube should be one of low vacuum, as the object is to obtain differentiation rather than penetration. In order to ensure shortness of exposure under these conditions the wattage of the secondary circuit must be high and the amount of the discharge sufficiently large. For this reason a coil giving a 10-inch or 12 inch spark answers better than a static machine. But I have known excellent results to be obtained, even in the case of the kidney, by very short exposure with a decidedly hard tube—and where the patient is very stout the tube must be hard. What is important, is not to obscure the differentiation obtained in the first few minutes' exposure by allowing too much penetration subsequently. The bowels must be cleared out thoroughly. All clothing containing foreign bodies likely to cast a shadow must be removed from the area to be examined. As a rule the patient should be placed in the recumbent position, with the plate, supported by a stout board beneath him, and an aluminium screen between the body and the tube. If it is wished to take a skiagram of the whole urinary tract at once the plate must be large enough to reach from the last dorsal vertebra to the lower part of the pelvis, but it is often better, when there is any doubt, to take two exposures, one of the kidneys and the upper part of the ureter, and the other of the lower part and the bladder.

One of the chief difficulties is the patient's breathing. The kidneys move up and down during even tranquil respiration to a much greater extent than is usually believed. They are not by any means immoveable organs, as anyone who has ever exposed a kidney during life must know. The patient cannot hold his breath for a sufficient length of time. The plan recommended by Mr. Mackenzie Davidson of making him hold his breath with the thorax fixed in a certain predetermined position, for short periods, at frequent intervals, and only allowing the exposure to take place at those periods, answers fairly well but requires a very careful patient. A more satisfactory plan is either to direct the patient to take very shallow breaths, or, better still, to put a firm bandage around the abdomen. This fixes it in a position of expiration and has the additional advantage of slightly raising up the opaque mass of the liver. The respiratory movement is less when the patient is sitting upright, but this advantage is more than compensated for by the way in which the abdominal viscera descend and conceal the kidneys. In the case of a very prominent abdomen the prone position, with the plate beneath, has been recommended instead of the supine position, with the idea that the abdomen would be flattened out to the sides and the kidneys brought nearer to the plate. I have had no experience of this, or of distending the stomach with carbonic acid gas—a plan which has been suggested as possibly of service in the case of the left kidney, under the impression that the more opaque viscera would be to some extent lifted from off it in front. Distension of the bladder with air in the case of a fixed vesical calculus is certainly of use, and provided the air is sterilised first, and due regard is paid to the sensations of the patient, it may be practised with no more danger or unpleasantness than that which attends the process of washing out the bladder.

The negative must be allowed to dry before any conclusion is drawn; and, if there is any doubtful spot, should be intensified with corrosive sublimate. Unless everything is certain a second examination should be made after a few days' interval, and if there is any doubt then a separate exposure should be taken of the area in question, a leaden plate with a circular opening exactly opposite the anode being interposed between the tube and the patient, so as to cut off as far as possible all extraneous rays and obtain a better defined shadow. I prefer plates in all cases to flexible films, as the latter are very liable to stretch when handled and give misleading results; but in such a case as that which I mentioned above in which there was an extreme lumbo-dorsal curvature they may be the more suitable in spite of this disadvantage.

Wimpole-street, W.

BRISTOL MEDICAL CHARITIES.—The employés of Messrs. W. D. and H. O. Wills of Bedminster, Ashton Gate, and Redcliff-street, have during the past 12 months voluntarily collected the sum of £389 18*s.* 11*d.*, which has been distributed amongst the Bristol hospitals and medical charities.

UROTROPINE AS A URINARY ANTISEPTIC.

BY P. J. CAMMIDGE, M.R.C.S. ENG., L.R.C.P. LOND.,
ASSISTANT DEMONSTRATOR OF PATHOLOGY, YORKSHIRE COLLEGE, LEEDS; LATE TREASURER'S RESEARCH STUDENT IN PATHOLOGY, ST. BARTHOLOMEW'S HOSPITAL, E.C.

EARLY in the year 1899 my attention was drawn to the effect produced by urotropine on the urine of a patient under the care of Dr. S. J. Gee in St. Bartholomew's Hospital. In the course of an attack of enteric fever he had developed cystitis, and his urine, which was markedly turbid from the presence of numerous typhoid bacilli and pus, had become quite sterile and clear after some six or seven doses of the drug. Subsequent observation showed that although many cases of cystitis arising from causes other than the typhoid bacillus were also markedly benefited by treatment with urotropine it was not invariably so. This led me to investigate the action of the drug on various micro-organisms and to attempt to determine the form in which it was excreted and the manner of its action in the urine.

Although urotropine or hexamethylene-tetramine ($C_6H_{12}N_4$) has long been known to chemists as a white crystalline body produced by the action of ammonia on formaldehyde it had not been employed therapeutically until Professor Nicolaier of Göttingen introduced it in 1894 as a diuretic and solvent of uric acid. He further claimed that it would prevent the development of bacteria in the urine.[1] On attacking the subject experimentally I first endeavoured to discover what effect urotropine had on the urine of a normal individual. For this purpose a healthy adult male was selected and the daily output of urine collected and measured for three weeks. Each day it was quantitatively examined for urea, uric acid, chlorides, phosphates, and sulphates. The specific gravity, reaction, and number of acts of micturition were also noted. The results obtained in the first and third weeks were only used as a standard with which to compare those of the second week, in which 10 grains of urotropine dissolved in an ounce of water were taken three times a day. During the whole course of the experiment the conditions as to food and exercise were kept as nearly as possible constant. It was found that the drug had not any diuretic action nor was any appreciable change in the excretion of the chemical constituents of the urine observed. Urotropine was found in the urine 10 minutes after the first dose was taken and it still continued to be excreted in small quantities 26 hours after the administration had been discontinued. One curious effect produced by the drug was a sensation of formication, which appeared on the fourth day and was most intense at night and in parts pressed on by clothing, &c. It became more intense each day and on the sixth day a diffuse red rash, somewhat like that of measles, appeared. Both rash and irritation quickly subsided after the urotropine was stopped. Usually urotropine is well borne, although Nicolaier speaks of 90 grains a day causing blood and epithelial cells to occur in the urine and a burning sensation to be complained of in the bladder. The urine passed during the first and third weeks on standing was found to quickly decompose, but that of the second week, which contained urotropine, remained clear and free from smell for more than four times as long.

All investigators are agreed that much of the urotropine taken by the mouth is passed unchanged, but there is considerable divergence of opinion as to whether the antiseptic properties of the urine are due to the drug itself or to some decomposition product arising from it. It is natural to suppose that if the latter is the case it is the formaldehyde which is set free to exert its well-known bactericidal powers. Löbisch, Casper, and A. Citron have stated that formaldehyde can be obtained from the urine, at any rate in most cases, but the last-named suggests that the active body is not free formaldehyde but a soda compound of it.[2] Free formaldehyde added to urine precipitates the urea and has been suggested as a means of estimating it. Further, the

characteristic smell of formaldehyde can never be detected in the urine of persons who are taking urotropine.

In working at the effects of urotropine on micro-organisms the bacillus typhosus, the bacillus coli communis, and the staphylococcus pyogenes aureus were employed. Active broth cultures of each of these organisms were prepared and one cubic centimetre added to nine cubic centimetres of a urotropine solution made up with sterile water and contained in a sterilised test-tube. Six strengths of urotropine were used—viz., 10 per cent., 7·5 per cent., 5 per cent., 2·5 per cent., 1·25 per cent., and 0·63 per cent. The 18 preparations thus obtained, together with three control tubes of one cubic centimetre broth and nine cubic centimetres water, were all incubated at 37° C. for 24 hours. At the end of that time they were searched in a good light for signs of growth and a specimen of each examined under the microscope. Sub-cultures of all the tubes into sterile broth were then made, and these, together with the original cultures, returned to the incubator. After a further period of 24 hours the examination of the original cultures was repeated and a similar process gone through with the sub-cultures. This proceeding was continued for 10 days. Cultures were also made containing the acid urine of a patient who was taking 10 grains of urotropine three times a day. Of this one, two, three, five, seven, nine, and 14 cubic centimetres were mixed with one cubic centimetre of active broth culture and the tubes in the first five cases made up to 10 cubic centimetres with sterile water. A third set of cultures containing formaldehyde 1·0 per cent., 0·5 per cent., 0·1 per cent., 0·08 per cent., and 0·04 per cent. were also made. These, as well as the preparations containing urine, were treated and examined in the way described above. The results are shown in the following table :—

		Control broth.	Formaldehyde.					Urotropine.						Urotropine urine, 30 grains a day.						
			1·0 per cent.	0·5 per cent.	0·1 per cent.	0·08 per cent.	0·04 per cent.	10·0 per cent.	7·5 per cent.	5·0 per cent.	2·5 per cent.	1·25 per cent.	0·63 per cent.	14 c.c.	9 c.c.	7 c.c.	5 c.c.	3 c.c.	2 c.c.	1 c.c.

NOTE.—In the above table the times 24 hours and 48 hours, &c., refer to the interval which elapsed between the preparation of the cultures and the first appearance of turbidity due to the growth of the micro-organisms.

Taking first the results produced by the urine, it will be seen that both bacillus coli and the staphylococcus pyogenes aureus grew well in the 14 cubic centimetre mixture, but that the typhoid bacillus was killed by 9 parts in 10. More dilute solutions, seven cubic centimetres and five cubic centimetres, were sufficient to prevent growth in the original culture, but that the bacillus was not dead, only inhibited, was shown by the slow growth which occurred in sub-culture. The series of experiments made with a simple urotropine solution showed that 7·5 per cent. killed the typhoid bacillus completely. The same strength prevented the growth of the bacillus coli communis in the original culture, but a perceptible growth had occurred in a sub-culture in 24 hours. A similar result was obtained with staphylococcus pyogenes, only the growth in subculture was delayed 48 hours. In a 5 per cent. solution no growth of the staphylococcus was seen until 48 hours had elapsed, and a similar result was obtained with a 2·5 per cent. solution in the case of the typhoid bacillus. Urotropine alone therefore in strong solutions appears to kill micro-organisms, but weak solutions only inhibit their growth—i.e., are kolyseptic. These experiments also bring out the varying susceptibility of different bacteria to the action of urotropine. The typhoid bacillus is much more susceptible than the bacillus coli and the staphylococcus pyogenes aureus. This is borne out by clinical experience. A few doses of urotropine will clear typhoid bacilli from the urine with ease and certainty, but the bacillus coli requires a longer and more vigorous course of treatment. The inhibitory action shown by urotropine is more markedly possessed, at least in the case of bacillus typhosus, by the urine passed by a person who is taking urotropine by the mouth. Formaldehyde in a 0·04 per cent. solution was found to be sufficient to kill both bacillus typhosus and the bacillus coli communis. A 0·08 per cent. solution was, however, required to destroy the vitality of the staphylococcus pyogenes aureus. None of the inhibiting action shown by urotropine and urotropine urine was observed in the case of formaldehyde. From these experiments it seems probable that the effects produced clinically in cystitis by urotropine are not due to free formaldehyde, but either to the urotropine itself or to some body closely allied to it.

It now remained to be seen whether formaldehyde could be obtained from the urine of patients taking urotropine; and secondly, to determine the condition under which it was liberated. In carrying out these experiments the following tests for formaldehyde were employed; (1) the pink colouration produced in a solution of resorcin in sodium hydrate; (2) Schiff's reaction (a pink or violet colour produced in a solution of rosaniline hydro-chloride decolourised by sulphurous acid); and (3) Fehling's solution.

Taking first a 12½ per cent. solution of urotropine in distilled water it was found that on heating it on the water bath with a strong acid (e.g., sulphuric) formaldehyde was liberated after from two to three minutes' boiling; with phosphoric acid the same result was obtained but more slowly; and with a 10 per cent. solution of caustic soda a faint reaction was given after half an hour. It was noticed, however, that boiling the urotropine solution itself for about half an hour also caused some decomposition with the liberation of traces of formaldehyde. In order to reproduce more nearly the conditions which obtain in the body, solutions of urotropine, urotropine with dilute sulphuric acid, urotropine with phosphoric acid, and a solution of urotropine to which dilute sodium hydrate had been added, were placed in small corked test tubes provided with a delivery tube which dipped below the surface of the test solution placed in a shallow dish. These, together with a control preparation of the indicating solution, were put into the incubator and left for 24 hours at 37° C. At the end of that time the test solutions connected with the tubes containing urotropine alone and urotropine with sodium hydrate were unchanged, the acid solutions had produced some change, which was, however, but slightly marked in the case of phosphoric acid. The test-tubes were now boiled on the water bath. With the acid solutions a marked intensification of the colour was quickly noticed, but with the urotropine and alkaline solution of urotropine only a feeble change was observed after about half an hour. The same methods of procedure were adopted with a normal acid urine to which urotropine and

the substances mentioned above had been added. On boiling it was found that the solutions to which acids and alkalies had been added gave off formaldehyde in about the same time as the corresponding watery solution, but that the mixture of urotropine and urine reacted more quickly than urotropine alone. In the incubator similar results to those of the first set of experiments were obtained and on subsequent boiling the only difference was the rapidity with which the acid urine decomposed the urotropine mixed with it. The acid urine of a patient who was taking 30 grains of urotropine a day was submitted to the same tests. By boiling the urine a formaldehyde reaction was obtained in about 20 minutes, dilute alkalies delayed the result for half an hour, but with acid it was well marked in from two to three minutes. On incubation no colouration of the test solution was found to have occurred except with the acid solutions. By boiling this colour was soon much more marked, but it was 20 minutes before the urine alone produced any change and about half an hour before the alkaline mixture gave evidence of the liberation of formaldehyde. Fehling's solution is readily reduced by formaldehyde, even in very dilute solutions, but is not affected by urotropine if the boiling is not too prolonged. A patient whose urine was known to be free from sugar was placed on urotropine 10 grains three times a day and the drug shown to be present in his urine by the abundant orange precipitate produced with bromine-water. On boiling a sample of this urine with Fehling's solution no reduction took place, showing that it did not contain free formaldehyde. By distilling an acid urine to which urotropine had been added formaldehyde was liberated and passed over in the distillate, as was shown by various tests. Ammonia was at the same time set free and "fumed" with strong hydrochloric acid held near the mouth of the condenser. A watery solution of urotropine and the urine of a patient on urotropine behaved similarly.

The results of these chemical experiments may be summarised as follows:—1. Urotropine alone may, by prolonged heating, be made to yield formaldehyde, but that this decomposition does not take place at body temperature. 2. An alkaline solution of urotropine may be similarly decomposed, but that the body temperature is not sufficient to cause the change. 3. Dilute acids quickly decompose urotropine on boiling with the evolution of free formaldehyde and that this change occurs to a less degree at 37° C. 4. Acid salts—e.g., of the urine—liberate formaldehyde from urotropine on boiling, but not at 37° C. 5. The acid urine of a person taking 30 grains of urotropine a day does not contain free formaldehyde.

Although the exact chemical nature of the antiseptic body occurring in the urine has not been definitely settled it seems clear, both from the bacteriological and chemical evidence, that it is not free formaldehyde. The readiness with which urotropine is decomposed by acids, and to a less extent by acid salts, together with the more marked inhibitory power over the growth of micro-organism shown by the acid urine over simple urotropine solution or an alkaline urine, would suggest that it is not the urotropine itself which is the most important factor in producing this kolyseptic action. It seems probable that acid urines produce in the kidney a partial decomposition of the urotropine by which some body is liberated, or a fresh compound formed which has very marked inhibitory powers over the growth of bacteria. If this hypothesis is correct an important point in securing the full effect of urotropine in bacterial infections of the urine would be that the urine should be acid in reaction as it leaves the kidney. That this is so is borne out by clinical experience. One condition in which it is preeminently useful I have already mentioned at the commencement of this article—namely, typhoid cystitis. Here the urine is generally acid and the administration of urotropine quickly causes the bacilli to disappear. It has also been found useful in cystitis accompanying enlarged prostate and stricture of the urethra. Here, too, the urine is usually acid as it leaves the kidney, and only becomes alkaline from the ammoniacal decomposition which takes place in the bladder. In suppurative pyelitis and in cystitis caused by calculus in the kidney or bladder a similar condition of the urine obtains, and good effects follow treatment by urotropine. The administration of urotropine as a means of insuring an antiseptic urine and an aseptic condition of the genito-urinary tract in operations on those regions has been highly recommended by Casper. Other conditions, such as bacteriuria and the nocturnal enuresis of children, the latter being said to be frequently caused by infection with the bacillus coli communis, would probably be found to be benefited by treatment with urotropine, since the urine is acid in reaction. Experience has shown that gonorrhœa and tuberculous cystitis are not appreciably benefited, but the conditions of the infection in these two diseases are different to those previously mentioned—the micro-organisms are not in the urine but lie chiefly in the tissues.

As a urinary antiseptic urotropine appears to be much superior to those usually employed (e.g, salol, ammonium benzoate, boric acid, guaiacol, naphthalin, and resorcin), especially when the acidity of the urine is insured by suitable means. It is not, however, only a curative agent in the ordinary forms of urinary infection that the advantages of the drug are so apparent, but in typhoid fever it may be employed from the third or fourth week onward to the advantage both of the patient and the community at large.[3] Recent researches have shown that typhoid bacilli occur much more frequently in the urine than has been generally supposed and that they may persist for very long periods after convalescence (five years).[4] By the systematic use of urotropine in all cases the very real danger from this source which is so frequently overlooked may be entirely avoided.

I take this opportunity of expressing my thanks to Sir Trevor Lawrence, treasurer of St. Bartholomew's Hospital, through whose kindness I have been able to conduct these experiments, and also to Dr. F. W. Andrewes for much kind advice and assistance as the work proceeded.

INFECTIVE PAROTITIS AFTER ABDOMINAL SECTION.

BY WILLIAM ELDER, M.D., F.R.C.P. EDIN.

IN THE LANCET of Dec. 29th, 1900 (p. 1873), Dr. B. Addenbrooke records a case of double parotitis after abdominal section from which apparently two other cases of parotitis originated. The following facts in connexion with a case at present under my care are interesting when considered along with Dr. Addenbrooke's cases.

A young man, aged about 20 years, was suddenly seized with pain in the right iliac region on Dec. 19th, 1900. On seeing him I diagnosed appendicitis, and on the 23rd he was operated on by Mr. H. J. Stiles of Edinburgh, who evacuated pus from the region of the appendix. The patient did well, the temperature continuing normal till the morning of the 26th, when it began to rise and he complained of stiffness and swelling in the region of the right parotid with intense pain. The swelling rapidly increased for about ten hours when the pain subsided. At this time the whole parotid region and upper part of the neck were enormously swollen, the swelling coming forward over the cheek and involving the eyelids, especially the under one. 36 hours afterwards (on the evening of the 27th) the left parotid began to swell in the same way, whilst the right parotid began slowly to subside. The left parotid attained to almost exactly the same size as the right and the temperature reached 103° F. The swellings were very painful to pressure, but there was no indication of suppuration in either of them. The second parotid reached its maximum in about 12 hours after it showed symptoms of enlarging. Both parotids gradually subsided and the swelling has now almost entirely disappeared. The wound in the abdomen is healing splendidly and the patient is doing well.

This was a case of parotitis following an abdominal operation. These cases are known to occur occasionally, but in the case here recorded there was a complicating circumstance. On Nov. 7th, 49 days before the onset of the first symptoms of parotitis in this case, I attended the patient's brother in the same house with mumps (double parotitis). The source of infection in this case I was unable to trace. The two brothers had been living in the same house from that date till the onset of the appendicitis, but they had occupied the same room for the first time on Dec. 17th, two days before the appendicitis commenced and nine days before the first

[3] Richardson Journal of Experimental Medicine, January, 1899. Horton Smith: Goulstonian Lectures, 1900.
[4] Dr. H. Cushing's case reported by Richardson, loc. cit.

parotid became inflamed. The seven weeks that elapsed between the commencement of the symptoms of parotitis in the two cases is certainly a greater length of time than usual, but I think one can hardly exclude infection from the first case as a cause of the second case. When considered with Dr. Addenbrooke's cases these cases are interesting, as in them the opposite condition from that found in those of Dr. Addenbrooke obtained—viz., there was a case of infective parotitis in the same house seven weeks before the onset of double parotitis following an abdominal wound, whilst in Dr. Addenbrooke's cases a double parotitis followed an abdominal section, and after coming in contact with the patient inflammation was set up in the second person's parotids. This second person again apparently infected a third person. As it is, I think, doubtful whether my second case was a case of true mumps or parotitis following an abdominal wound, so I think it must also be doubtful whether Dr. Addenbrooke's first case was one of parotitis caused by the abdominal wound or a case of true mumps due to infection the source of which he was unable to trace; just as in my first case of mumps I was unable to trace the source of the infection.

Leith, N.B.

A CASE OF GANGRENE OF THE PENIS.

BY GEORGE A. CLARKSON, F.R.C.S. ENG.

GANGRENE of the penis occurring as a complication of any illness is necessarily of extreme rarity and has only been known to occur in conditions of great vital depression. It is mentioned as occurring occasionally in cases of typhus fever and it has been known to follow paraplegia. However, very few cases have been described and most surgical works do not even refer to it. In the present instance a feeble and dilated heart, extensive atheroma of the arteries, possibly inoculation of some part of the urethra with infective organisms, were the determining factors.

The patient, aged 51 years, employed in an iron foundry, had suffered severely from chronic bronchitis every winter for 15 years. For some years he had only been able to work in the summer months and latterly had so lost ground that he had been obliged to give up work even then. He emaciated considerably; his aspect became yellow and cadaverous, cough and expectoration were constant, and there was more or less complete loss of appetite and also some œdema of the legs. Examination of the chest revealed much emphysema, exceedingly feeble and distant heart sounds, and a slight impulse outside the nipple line; no murmur was audible. The temporal and radial arteries were very tortuous and rigid and the pulse was feeble and intermittent. In this condition he remained till Sept. 28th, 1899, when he suddenly became very faint and collapsed. He was put to bed and wrapped in blankets. When seen he was barely conscious, the extremities were cold, the heart sounds were inaudible, and the pulse was hardly perceptible. With cardiac and general stimulants he rallied and seemed to be better for some days. The tongue, however, remained coated and dry, there was some muttering delirium at night, and the urine, which had been ammoniacal and offensive, became more so now that he was confined to bed. On Oct. 11th he complained of considerable pain in the penis, which was much swollen all over. There was no phimosis or sore under the prepuce. On the 13th several gangrenous patches appeared and during the next day or two the whole organ became involved. Five incisions were made deep into the tissues with the view of relieving any possible tension, but there did not appear to be any; the deeper parts of the organ seemed to be equally affected and only a small quantity of dark fluid was discharged into the dressings. The whole organ appeared to be in a condition of ordinary moist gangrene. Owing to his general condition no further operative measures were deemed advisable. Continuous hot boric fomentations were applied and immersion was given in a hot boric bath; opium, carbonate of ammonia, and digitalis were given internally. The patient died on Oct. 16th, the whole organ being completely gangrenous.

It seems hardly credible that an organ with the anatomical peculiarities of the penis could be the subject of dry gangrene, yet such has occurred. In the case of a patient under the care of the late Mr. Partridge at King's College Hospital[1] gangrene attacked the penis and the organ became black and charred-looking. A line of demarcation formed, urine issued at this point, the penis dropped off, and the patient made a good recovery. His age was only 40 years.

ST. THOMAS'S HOSPITAL

TWO CASES OF SARCOMA OF THE BREAST.

(Under the care of Mr. W. H. BATTLE.)

TRAUMATISM as an etiological factor in the appearance of sarcoma is now generally accepted, although it is not possible to offer any very satisfactory explanation of the manner in which an injury gives rise to the new growth. In many cases the sarcoma appears before the swelling caused by hæmorrhage or inflammation has completely subsided, and it is possible that these effused products form a suitable nidus for the development of the neoplasm. True sarcomata of the breast are certainly not common, and the two interesting cases recorded below are in many ways noteworthy; especially remarkable is the age of the patient in the second case—namely, 13 years.

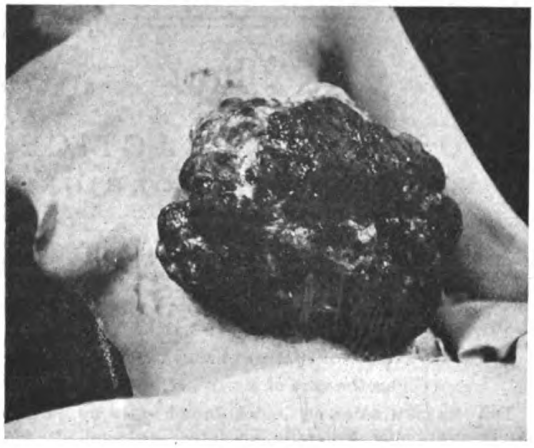
CASE 1.—A woman, aged 36 years, was admitted into St. Thomas's Hospital on June 8th, 1900, complaining of a tumour of the breast. About 14 months before admission she had received a blow on the left breast, which became tender and was much bruised. Soon after this she suffered from a sharp pain in that breast, worse in damp weather, and she also noticed that a swelling was present. She therefore consulted a medical man who prescribed some medicine. The swelling in the breast grew steadily larger and she took to her bed. About ten days before admission the patient got up and had a severe hæmorrhage from the breast and therefore had to take to her bed again. After this she was so weak that she fainted whenever she sat up. A week before admission the breast began to fungate and then grew rapidly. The only point in her family history of any importance was the statement that an aunt on the mother's side had had "cancer of the breast" for a year and was still alive.

On admission the patient was very thin and anæmic and had an anxious expression. The left breast was the seat of a large mushroom-like fungating tumour with an offensive, thin, bloody discharge (see figure). The tumour was flattened, with a margin which was much everted. The breast itself was not much enlarged and formed a kind of pedicle for the expanded part; this pedicle was narrower from within outwards than from above downwards. The surface of the tumour was nodular and blackened. In the left axilla one enlarged gland could be felt. The other organs were quite normal.

On June 11th Mr. Battle operated. The narrowness of the attached portion of the breast already mentioned was utilised; it was clamped like a pedicle with two long-bladed forceps passed from above and from below in the line of the pectoralis major. The growth was cut away close to the forceps and the breast was then excised. The axillary gland was not touched, as its enlargement was supposed to be due to septic absorption from the surface of the tumour. Very little blood was lost during the operation and this was so thin and pale that it produced merely yellow staining of the aseptic cloths which surrounded the operation area. There was apparently no tendency to infiltrate the breast substance—in fact, the breast itself appeared to be quite small and really not much larger than the opposite one.

[1] Medical Times and Gazette, vol. xx.

On June 12th the patient felt quite well and had had a good night; on the 13th the wound was dressed—it looked very healthy. Later there was a slight discharge from the wound and a small abscess formed at the upper part of the incision, but by July 3rd the wound had almost healed and



she left the hospital the next day. She was seen on August 27th and it was found that her general condition had much improved. The gland in the axilla was no longer noticeable. The report of the microscopic examination of the growth stated that it was a round-celled sarcoma.

CASE 2.—A girl, aged 13 years, was admitted into St. Thomas's Hospital on July 5th, 1900, complaining of a swelling of the right breast. Two months before admission the patient received a blow on the right breast, and soon afterwards she noticed a small lump in that breast, which, after a short time, went away spontaneously, but a week or so later she noticed a swelling "as large as a nut" in the same place. This gave her occasional pain and gradually increased in size. The case had at first been treated as a mastitis There was nothing of any importance in either the personal or family history.

On admission the right breast was found to contain a prominent, somewhat bossy swelling; it was of about the size of a Tangerine orange and was freely moveable on the deeper structures. It was surmounted by the nipple, where it was also most painful, though at times it gave her no pain at all. On palpation a slight amount of fluctuation could be felt just above the nipple. The skin was nowhere bound down to the swelling except immediately below the nipple. The most striking feature about the breast was the bold manner in which the tumour stood out from the chest-wall, in marked contrast to the ill-developed breast on the other side. Nowhere in the breast was there any sign of inflammation. In the axilla a few glands might be felt, although they had not attained any considerable size. The urine on examination was found to contain a trace of albumin and blood and a doubtful trace of sugar.

On July 13th Mr. Battle operated. He made an oblique incision about six inches in length from the anterior axillary fold downwards and inwards, passing about an inch below the nipple The two ends of this incision were connected by another which passed about an inch above the nipple. The tumour was then dissected out with the whole of the breast and much of the surrounding fatty tissue. The fascia covering the pectoralis major was also removed. The two edges of the skin were then united by salmon-gut sutures and the wound was dressed with dry cyanide gauze. The patient bore the operation well and no rise of temperature occurred at any time and the wound was not dressed until the 19th, when it was found to have healed almost throughout its length. She was discharged from the hospital on July 21st. The report from the clinical laboratory stated that it was an adeno-sarcoma.

Remarks by Mr. BATTLE.—The report from the Clinical Laboratory on the first case describes the growth as a round-celled sarcoma. This may be correct but there are one or two points which suggest the possibility of it being a simple fungating growth from within a cyst. These are (1) the small involvement of breast tissue; (2) the absence of glandular disease; (3) the absence of any other growths; and (4) the fact that the history was rather long for a round-celled sarcoma. On the other hand, the history of injury and the report of the microscopical examination are in favour of the growth being a sarcoma.

The second case was traumatic in origin and is one of the youngest of the kind on record. The way in which the tumour stood out from the surface was very striking and quite unlike the appearance presented by mastitis. The absence of œdema was also noteworthy. Sheild[1] describes one case of myxo-sarcoma at the age of six months, the specimen being in the Royal College of Surgeons of England. He also recorded a case for the late Sir George Humphry, the patient being 14 years of age; this was a spindle-celled growth.

GOVERNMENT CIVIL HOSPITAL, HONG-KONG.

TWO CASES OF RUPTURED SPLEEN; ABDOMINAL SECTION; ONE RECOVERY AND ONE DEATH.

(Under the care of Mr. J. BELL, Acting Principal Civil Medical Officer.)

EXCISION of the spleen for disease is an operation with an extremely high mortality and it is doubtful if recovery has ever followed when the operation has been done for leucocythæmia. For injury, however, excision of this organ is an extremely satisfactory operation, and even in pre-antiseptic days cases occurred in which a spleen extruded through a wound of the abdominal wall was removed after its pedicle had been tied.

CASE 1.—A Chinese male adult was admitted into the Government Civil Hospital, Hong-Hong, on Sept. 6th, 1900, at 12.45 P.M., having been assaulted in the early morning. He was much collapsed and in great pain, chiefly referred to the epigastrium. There was well-marked dulness in both flanks and he had a quick small pulse. Assisted by Captain Wall, I.M.S., the abdomen was rapidly opened in the middle line under strict antiseptic precautions, the spleen was removed, and the peritoneal cavity was thoroughly cleared out with warm sponges. During the operation Dr. Thomson of the Royal Army Medical Corps and Lieutenant J. W. F. Rait, I.M.S., kept up transfusion, which proceeding very materially contributed to the successful result. The spleen weighed 16 ounces and was torn right across. At 9 P.M. the patient had rallied from the shock and was very comfortable. On the third day, owing to great distension, the wound gaped, so the patient was again put under an anæsthetic and several more stitches were inserted. Free purging soon removed the distension. The patient recovered slowly, the wound healing well. On Oct. 20th he was well enough to attend at the police-court and on the 27th he left the hospital.

CASE 2.—A Chinese male, aged 27 years, was admitted to hospital at 10 A.M. on Sept. 19, 1900, having been mixed up in a free fight. He had been kicked and struck on the abdomen and head. The patient was not much collapsed but complained of great pain over the abdomen. He slowly got worse all day, and at 8 P.M. there were well-marked signs of internal hæmorrhage. Owing to the delay of taking his dying depositions it was not possible to interfere till midnight. Assisted by Dr. G. P. Jordan, who before the operation began transfused two pints of saline fluid into the cellular tissue of the axilla, the abdomen was opened in the middle line, the spleen was removed, and blood-clots were cleared out. The organ weighed 18 ounces and the rupture had occurred beneath the capsule which was completely raised from the surface and had ruptured close to the hilum. 24 hours later the patient had completely recovered from the shock. His pulse had improved under strychnine and camphor and he expressed himself as feeling quite comfortable. On the following day, however, cerebral symptoms set in. with gradually increasing coma, great restlessness, and a rising temperature, till 8 P.M., when he died, the temperature being 106° F. and the pulse 148.

Necropsy.—At the post-mortem examination the abdomen was found to be clean and the ligature was quite fast on the stump. There was much extravasation in the muscles behind the right ear. Exactly opposite on the left side there was a fracture running through the petrous portion of the

[1] Diseases of the Breast.

temporal bone to the base of the skull. There was a large clot pressing on the medulla.

Remarks by Mr. BELL.—These cases will serve, I hope, as an encouragement to others to operate even after a long interval has elapsed since the accident. Transfusion early undoubtedly helped greatly to the successful result.

Medical Societies.

MEDICAL SOCIETY OF LONDON.

The Value of Skiagraphy in the Diagnosis of Chest Disease.

A MEETING of this society was held on Jan. 14th, Mr. JOHN H. MORGAN, the President, being in the chair.

Dr. HUGH WALSHAM and Dr. E. CLIFFORD BEALE communicated a paper on the Value of Skiagraphy in the Diagnosis of Chest Disease, illustrated by skiagrams of various morbid conditions within the thoracic cavity. In order to obtain a satisfactory shadow either upon the fluorescent screen or the sensitive plate it was absolutely necessary to employ a powerful coil capable of yielding a 12 or 14 inch spark. The patient should lie on a couch face downwards, the sensitive plate, duly protected from light and injury, being placed under the chest and the tube from two to three feet above it, great care being taken that the anti-cathode in the tube should be placed exactly vertical to the part of the chest to be examined. Stereoscopic views could be obtained by means of Mr. Mackenzie Davidson's apparatus. An exposure of two minutes was, as a rule, sufficient in the case of the chest, but the greater the distance of the tube from the object the longer should be the exposure. In observations with the fluorescent screen the tube must of necessity be closer to the chest-wall, and allowance had then to be made in interpreting shadows for the apparent enlargement of the tissues lying nearest to the tube owing to the divergence of the rays. It was always advisable to examine with the screen at the back as well as at the front, and useful information could often be obtained by diagonal observations. No danger need be apprehended where the rays were only passed for a few minutes at a time. Cases of dermatitis had from time to time been reported, but in such instances the exposures had been excessive—viz., from half an hour to two hours. In order to interpret morbid shadows it was necessary to study those thrown by the normal thoracic structures. Several skiagrams of healthy chests were then thrown upon the screen, in all of which the shadows of the heart, diaphragm, and mediastinal tissues were clearly seen, but in addition to them certain faint streaks by the left side of the heart and both sides of the mediastinal shadow. These had been shown by Dr. Walsham's and Dr. Beale's observations to be due to the pericardium and visceral pleura. The shadow of the scapulæ, the anterior axillary fold, and in some cases of the nipple might be recognised as normal, but they were easily identified by moving the arms. Healthy lungs were shown to be translucent. It had long been recognised that advanced tuberculous changes showed definite shadows, but the very earliest deposits of tubercle did not yield any appreciable shadow. Cases were quoted and exhibited proving that tuberculous shadows could be detected before the presence of tubercle was indicated by any abnormal physical signs, and that in suspected early cases where no shadow appeared there was no subsequent evidence that the disease was actually present. In cases that had been presumed to be unilateral disease a shadow was sometimes to be found at the other apex also and in many such instances the extent as well as the presence of the disease could be clearly defined. The more advanced the disease the darker the shadow, especially where caseation was in progress. Cavities were indicated by light areas in the midst of dense shadows. Fibroid changes and adhesions only gave rise to a shadow after they attained to a definite density and the shadows differed considerably from those thrown by tubercle. Emphysema was indicated by exceptional translucency of the affected parts of the lung. In early dry pleuritis only a very faint shadow could be detected. Serous effusion caused faint blurring of the rib shadows but did not obliterate them; the upper margin of the fluid frequently showed a clear line of demarcation. Purulent effusion, on the other hand, caused very dark shadows. A tube of pus removed from the pleural cavity gave a shadow almost as dark as that of a bone of equal calibre, very much darker than the shadow of a similar amount of fluid blood or of serum. Abscesses, like caseating nodules, threw dark shadows, and caseous tuberculous nodules were clearly discernible even through thick tissues such as the kidney. In heart diseases the rays were of less diagnostic value, but much more observation was necessary on this point. By far the most important use of skiagraphy in chest disease was for the detection of morbid growths and aneurysms. Many examples of the latter were shown where the evidence afforded by the rays was far more precise and definite than that obtained by the ordinary methods. By means of the skiascope the movements of the heart and diaphragm could be watched, and the condition of aneurysms, whether full of dark clot or semi-translucent fluid blood, with the extent and position of their maximum pulsation, could be determined with considerable accuracy. Much more work remained to be done on the subject and the paper was put forward only as a preliminary statement of the observations already made.

The PRESIDENT remarked that the art of radiography was still in its infancy and a contribution like that before the society was highly welcome. He hoped that it would elicit further information from the members present.

Dr. H. LEWIS JONES congratulated Dr. Walsham and Dr. Beale upon their paper. He had seen a great deal of Dr. Walsham's work and he was a most painstaking observer. He had no doubt about the value of radiography. If he were doubtful about a case of early pulmonary tuberculosis he would rather have a skiagram than the opinion of the best auscultator on the case. It was no doubt necessary to have some experience and knowledge to be able to read the different shadows in skiagrams, but a little practice rendered a person skilful in this respect. No doubt by-and-by an apparatus of this kind would become a necessary part of a physician's means of observation and they should by-and-by be able to set aside the stethoscope. As to aneurysm, the disease had within his experience been revealed both in unsuspected cases and in cases which were only suspicious.

Dr. A. E. SANSOM was entirely in favour of the use of radiography. He had used it very often and attached great value to it, but he could not agree with the suggestion of doing away with the stethoscope. Auscultation, palpation, and percussion would always remain valuable means of physical diagnosis and the x rays were a valuable supplementary method but could not replace the others. He remembered, however, one case in which the x rays clearly showed a bulging aorta in which the physical signs and other symptoms were absolutely negative.

Dr. J. KINGSTON FOWLER wished to emphasise the necessity of using the very best apparatus procurable. Short sparks were no use. He quoted cases of pulmonary tuberculosis in which the x rays had been of considerable use, but he was afraid that on some occasions the first rib came in the way of diagnosing disease at the apex. Radiography was a valuable means of diagnosis but he did not think exaggerated claims should be made for any one method.

Dr. BEALE, in reply, said that Dr. Walsham had done the practical work in connexion with the paper and it had required great perseverance to accomplish. He personally did not advocate the replacement of the older methods. He regarded radiography as simply an adjunct to them. He hoped that in spite of the expense the apparatus would soon become a necessary and routine means of investigation. He spoke very highly of Mr. Mackenzie Davidson's spectroscopic apparatus and he concluded by demonstrating the diagonal method of examining the chest. This was, he said, a novel and valuable means of examining certain cases. It had been employed at Nice and Vienna but had not hitherto been employed in England.

PATHOLOGICAL SOCIETY OF LONDON.

Cirrhosis Maligna.—Primary Cancer in a Cirrhotic Liver with Metastasis in the Lungs.—Primary Carcinoma of the Liver associated with Cirrhosis.—Cirrhotic Liver the seat of Secondary Carcinoma.—Chronic Cholangitis in a Child.—Localisation of the Bacilli of Leprosy.—Adenomatous Papilloma of the Sigmoid.—Chondro-sarcoma of the Tibia associated with Pendulous Bodies.—Malignant Disease of the Suprarenal Body.

A MEETING of this society was held on Jan. 15th, Mr. W. WATSON CHEYNE, the President, being in the chair.

Dr. H. D. ROLLESTON read a paper on a case of Primary Carcinoma in a Cirrhotic Liver (Cirrhosis Maligna or Cirrhosis Carcinomatosus). The patient was a man, aged 44 years, who during life had hæmatemesis, pain in the hepatic region, and ascites which required tapping on four occasions. At the necropsy the liver was the only organ showing any new growth; it was universally cirrhosed, weighing 52 ounces, and in addition presented a white gelatinous growth projecting from the right lobe which by invading the liver substance had grown directly into the bifurcation of the portal vein; the growth had travelled along the portal vein and given rise to secondary carcinomatous nodules in the liver. Microscopically the tumour was formed of deeply staining cells arranged in the form of twisting tubules with obliterated lumina; the tubules were separated from each other by capillaries, had an irregular arrangement, and corresponded to the form of carcinoma described by Hanot and Gilbert as "Épithéliome trabéculaire." These writers regarded the growth as synchronous with, and due to the same cause, as the cirrhosis. Sabourin, with whom Dr. Rolleston agreed, regarded the cirrhosis as the earlier change. It seemed possible that the growth was a further development of the so-called new bile-ducts which in reality might be considered in the light of a compensatory hyperplasia of the liver-cells. The growth might, therefore, like chronic endarteritis, be regarded in the light of a hyperplasia that failed. Possibly this malignant change was due to infection with the—as yet undiscovered—parasite of cancer. Sections of the portal vein showed its lumen to be filled with the same growth, and on this the diagnosis of malignancy and the distinction from cirrhosis complicated by adenoma depended.

Dr. WILLIAM HUNTER made a communication on two cases of Primary Cancer in a Cirrhotic Liver with Metastasis in the Lungs. The first was that of a man, aged 60 years, who was admitted for dropsy and ascites after an illness of only six weeks' duration. The second case was a man, aged 55 years, who was admitted for jaundice with ascites after an illness of three months duration. Both the patients were tapped, but a fatal issue resulted. In both cases the liver was the seat of (1) coarse multilobular cirrhosis, (2) islets of apparently healthy liver cells, (3) deposits of cancer cells in some of these islets, and (4) thrombosis of the branches of the portal vein. In both cases there were metastatic deposits in the lungs of the same neoplasm which presented a markedly tubular character. Dr. William Hunter expressed the view that the neoplasm originated from the liver cells by the direct transformation of the latter. Many of the cells were multinuclear and presented evidence of extreme activity. The growths in the lungs resembled in a very remarkable way the new growths in the liver.

Dr. CAMPBELL THOMSON showed a specimen of Primary Carcinoma of the Liver associated with Cirrhosis which occurred in a man, aged 40 years. The liver was much enlarged and weighed 85 ounces. The right lobe was almost entirely infiltrated with new growth, which formed, also, a large central raised mass from which nodules of various sizes radiated. There was extensive thrombosis of the portal veins. The liver was cirrhotic and showed typical projections on its surface and on section. There were numerous secondary growths in both lungs and in the lymphatic glands. During the past two years Dr. Thomson had made 170 post-mortem examinations upon cases of malignant disease at the Middlesex Hospital, and out of these had found only three cases of primary carcinoma of the liver of which only this one had been associated with cirrhosis. He thought, from the appearance of the growth, that the simultaneous occurrence of the carcinoma and the cirrhosis in this specimen was probably a coincidence.

Dr. H. MORLEY FLETCHER exhibited a Cirrhotic Liver the seat of Secondary Carcinoma taken from a man, aged 54 years, who had been admitted for cirrhosis with ascites. In this case the carcinomatous deposit was a secondary growth and in that way differed from the cases of the previous speakers. The liver also showed a remarkable malformation of the gall-bladder, which was attached to the upper surface of the right lobe of the liver.—The PRESIDENT asked Dr. Hunter whether he actually saw the continued development of cancer cells from the liver cells or whether he only inferred that the change took place.—Dr. A. G. AULD remarked that the statement by Dr. Hunter that the liver cells were directly transformed into carcinomatous cells was open to grave doubt. It had been held by some pathologists that the liver cells themselves were derived from the mesoblast and transformation of hepatic cells into connective tissue had been described by Hamilton and others. He thought there was much probability in this. Some years ago he had met with a case which had first given him the impression that cancer cells had been developed from liver cells, but further investigation showed such hypothesis to be fallacious.—Mr. S. G. SHATTOCK had met with cases of this class. He had never seen any difficulty in recognising the fact that carcinoma could arise from liver cells. He had always been under the impression that the liver was a structure of hypoblastic origin. There were, in point of fact, two classes of hepatic carcinoma—one which arose from the ducts and another, the spheroidal-celled class, which was derived directly from the liver cells.—Mr. C. A. BALLANCE asked what was the exact difference between a normal cell and a cancer cell in the liver.—Dr. HUNTER, in reply, said that he did not mean to imply that there was a total transformation of a mass of liver-cells into cancer, but in certain islets there could be seen an extension from cell to cell of the carcinomatous characters. The difference between a normal liver-cell and a cancer-cell was very striking. The former underwent enlargement and presented differences of staining, especially in the nuclei.

Dr. H. MORLEY FLETCHER also exhibited specimens taken from a case of Chronic Cholangitis. The patient was a child, aged three and a half years, who was admitted to St. Bartholomew's Hospital, under the care of Sir William Church, suffering from severe dyspnœa. The illness had begun two weeks previously with cough and on admission the respirations were from 80 to 90 a minute. The liver was enlarged, but there was no jaundice or any other symptoms pointing to disease of that organ. The child died four days later. The lungs were in a condition of acute bronchiectasis, similar to that shown to the society by Dr. H. H. Tooth some years ago. The liver contained pale areas of fibrous tissue surrounding the bile ducts, with numerous cystic spaces filled with bile-stained débris. There was evidence of a pericholangitis, of long-standing, as shown by the development of well-formed fibrous tissue with formation of new bile ducts therein. In places an acute cholangitis had occurred with destruction of the bile ducts and formation of a cyst containing bile-stained material. The origin of the lesions was obscure. No evidence of syphilis could be obtained.—Dr. HUNTER asked if there had not been any jaundice? He had recently seen a case somewhat resembling this one of infective cholangitis occurring in a man. This case had been less chronic in character.—Dr. ROLLESTON recalled a case which he had seen three years before of a man, aged 48 years. The liver had not presented white lumps softening in the centre, but there was evidence that two changes had taken place in the liver: (1) a cholangitic and (2) a streptococcal infection of the lymphatics, by which means the portal veins had become infected and the seat of thrombosis. He thought that the lymphatics played a prominent part in the pericholangitic changes.—Dr. FLETCHER, in reply, said he did not place any special importance on the fact that his patient was a child. He thought Dr. Hunter's suggestion a very good one and that the lymphatic system played a very great part in the process.

Mr. GEORGE PERNET read a paper entitled "The Bacilli of Leprosy: Are they Extra- or Intra-cellular?" Most observers and writers were of opinion that the colonies observed in sections of tissues were situated within the cells. Mr. Pernet opposed this view and on this point agreed with Unna, Leloir, and others who contended that the masses were extra-cellular. The so-called lepra cells were not cells at all, but glœal masses of bacilli. He (Mr. Pernet) had examined many microscopical preparations of leprous tissues and his conclusion was that the great majority of the bacilli were in the intercellular and lymphatic spaces; that was to say, were extra-cellular. As to the meaning of the glœal masses, he expressed the belief that they were a stage in the life-history of the bacillus lepræ, just as a similar stage had been demonstrated, for instance, in connexion with cladothrix dichotoma (of Billet). It was probably a resting stage, during which the parasite prepared for further proliferation. This agreed with the clinical experience of leprosy, in the course of which fresh eruptions and exacerbations were frequently observed. The paper was illustrated by microscopical preparations.—Dr. F. W. ANDREWES remarked that three years ago the

late Professor Kanthack brought before the Pathological Society of London a series of sections to demonstrate that many of the so-called leprous cells were in reality only lymphatic spaces stuffed with clumps of bacilli. He had specimens in his possession which showed that at any rate in the spleen certain of the true splenic cells contained bacilli. Some were distributed outside but certainly some were within the cells.—Mr. S. G. SHATTOCK confirmed the last speaker and said that in the lymphatic glands he had found the same intracellular distribution. It was a fact beyond dispute that some of the cells contained bacilli and some of these were undergoing vacuolation.—Mr. PERNET, in reply, said that he quite admitted the fact that the bacilli might be both extra- and intra-cellular, but the point he wished to establish was that in the majority of instances they were extra-cellular. He also wished to emphasise the fact that these so-called leprous cells were masses of bacilli and not true cells.

Mr. PHILIP DE SANTI read notes of a case (and exhibited the specimen) of Papillary Adenoma of the Sigmoid Flexure. The patient, who was 51 years of age, had been under the care of Dr. R. G. Hebb for some months as an out-patient and had suffered from constipation and diarrhœa, pains in the abdomen, occasional vomiting, and passage of blood and "slime" per rectum. In 15 months he had lost two and a half stone in weight. In the left iliac fossa could be felt a fairly distinct hard lump, evidently intra-abdominal and connected with the sigmoid flexure. Malignant disease was suspected, and in September, 1900, Mr. de Santi opened the abdomen and the sigmoid flexure, exposing a small tumour which turned out to be a simple pedunculated papillary adenoma. The tumour was removed, the gut was closed with Lembert's sutures, and the patient made an uninterrupted recovery. The points of interest in the case were, first the train of symptoms which, together with the feel of the tumour were strongly suspicious of malignant disease; and secondly, the rarity of a tumour of this sort as a solitary growth of the sigmoid flexure.

Mr. S. G. SHATTOCK exhibited the Knee-joint of a woman operated upon by Mr. C. Stonham for a Tumour of the Head of the Tibia. On the bone being sawn through after amputation, there was found a large tumour in the head of the tibia and others of smaller size in the lower end of that bone and the lower end of the femur. The tumours were of the calcifying chondro sarcomatous kind. The interest of the specimen, however, related to the presence of pendulous bodies which projected from the synovial membrane of the knee-joint; these presented precisely the same structure as the growth in the head of the tibia. The same doubt as to the explanation of such association existed now as when Virchow discussed the subject of multiple chondromata in his lectures. Mr. Shattock held that both the possible views were correct in different cases. According to one view all the lesser growths in the present case would be metastatic to the chief tumour in the head of the tibia. The other view was that a sarcomatous metaplasia had affected several dormant foci of cartilage independently. The cartilage cells present normally in the synovial fringes of joints were as much fœtal, or developmental, relics as the foci that might remain in the ends of the long bones, since they dated from the liquefaction of tissue whereby the articular cavities were formed between the cartilaginous bases of the bones. The pendulous bodies in the present specimen contained areas of such well-developed cartilage that what had happened was probably a sarcomatous transformation like that which had occurred in the head of the tibia, and in a considerable area of the centre of the tumour, which consisted of pure hyaline cartilage and represented an intra-osseous chondroma. The same doubt obtained in the condition which had been named by Garré "secondary malignant neuroma." In some of these cases the sarcomata of the nerves appeared to be metastatic upon a sarcomatous transformation in a nerve-fibroma; in others they appeared to arise independently in pre-existing fibromata of the nerves. In the second class of case the sarcomatous transformation occurred in tumours so widely separated (the disease being still confined to the nervous system) that a metastatic infection was hardly credible; in the first class of case the recurrences involved a series of nerves centripetally, and here the passage of infecting cells by the lymph channels of the nerves themselves would serve to explain why the metastasis was for a long while limited to the nervous system though visceral disease might ultimately ensue.—The PRESIDENT wished to understand whether these tumours were malignant or not. It did not necessarily follow that because a structure showed sarcomatous growth a tumour was malignant.—Dr. W. S. LAZARUS-BARLOW remarked that there was a second deposit at the lower end of the tibia. This with the secondary growths in the pendulous bodies showed the case to be malignant, but it was limited to the lower segment of the lower limb.

Dr. O. K. WILLIAMSON exhibited the Right Suprarenal Body from a woman, aged 51 years, which was completely involved in a mass of new growth, the primary deposit having occurred in the mediastinum.

CLINICAL SOCIETY OF LONDON.

Fatal Pancreatic Cyst of Enormous Size simulating Ascites —Subacute Combined Degeneration of the Spinal Cord in Association with Pernicious Anæmia.—Syphilitic Disease of the Aortic Valve.—Rheumatic Periostitis with Subcutaneous Nodules.

A MEETING of this society was held on Jan. 11th, Sir R. DOUGLAS POWELL, Bart., the President, being in the chair.

Dr. SIDNEY PHILLIPS read the notes of a case of Fatal Pancreatic Cyst of Enormous Size simulating Ascites. The patient, a man, aged 22 years, received a kick in the abdomen from a horse causing intense pain which confined him to bed for a time. After this he was subject to occasional acute attacks of abdominal pain, and five months later he was admitted into St. Mary's Hospital, very emaciated, without pyrexia, but with an enormously tense distended abdomen, dull on percussion everywhere except in the area of the stomach. There was a fluid thrill and eversion of the umbilicus; the percussion dulness did not alter quite so freely with altered positions of the patient, as was usual in ascites, but it seemed probable that it was a case of ascites with peritoneal adhesions. The patient became gradually worse, and after 145 ounces of fluid had been drained off by Southey's tubes there was no improvement. A few days later, therefore, an incision in the abdominal wall below the umbilicus was made and a large quantity of fluid like that of ascites was let out; the wound healed up but the patient continued to get worse and died a few days later. The necropsy showed that the fluid had been contained in a huge cyst of the pancreas occupying nearly the whole of the abdominal cavity and coming forward close to the abdominal wall. The stomach was above the cyst and the margins of the two structures were closely adherent; downwards the cyst extended to the pelvic brim. The cyst had originated in a communication one-sixth of an inch in diameter in the head of the pancreas. Dr. Phillips commented on the enormous size of this cyst, which virtually filled the whole of the abdominal cavity, and was indistinguishable during life, and without careful dissection after death, from ascites. The contained fluid had a specific gravity of 1002; it was clear and slightly yellow in colour, was exactly like that in ordinary ascites, and was different from that generally contained in pancreatic cysts. Neither tapping nor laparotomy could have been expected to effect a cure in such a case even if its nature had been known.—Mr. NEWTON PITT remarked that an interesting feature of the case was the enormous size of the cyst, such cysts, he added, sometimes presenting above and sometimes below the transverse colon. He asked in which position it appeared in Dr. Phillips's case. The nature of the fluid was to him the most noteworthy feature in the case. In all recorded cases of pancreatic cyst the fluid had been turbid with much débris, and it was very striking that in this case the fluid should have been clean, with a specific gravity of 1002, exactly resembling ascitic fluid. He thought the circumstance needed explanation. Referring to the digestive action of the fluid on the tissues with which it came into contacts he remarked that this made the case under consideration even more unusual.—Dr. J P ZUM BUSCH mentioned a somewhat similar case which he had seen nine years ago. On admission the case was thought to be one of cirrhosis of the liver, and upwards of five litres of clear fluid were withdrawn which turned starch into sugar. He remarked that it was highly dangerous to tap in these cases. In the case to which he referred the patient subsequently died from septic peritonitis and at the

necropsy it was found to be a case of pancreatic cyst.—Mr. A. E. J. BARKER asked what was the exact relation of the tumour to the stomach; sometimes these cysts presented above and sometimes below that organ. Rupture of such cysts generally proved fatal and they certainly ought not to be treated by puncture but by incision.—The PRESIDENT referred to a case in which puncture was resorted to under the impression that there was ascitic fluid. In another case a very large pancreatic cyst was taken to be hydatid and was incised; then a correct diagnosis was made and the patient recovered. He subsequently developed glycosuria and died from diabetes.—Dr. PHILLIPS in reply, said he had brought the case forward as one in which the diagnosis had not been made and consequently not as guide to treatment. He regretted that no chemical examination of the fluid had been made during life, and at the necropsy it was not possible to procure any of the cyst contents.

Dr F. E. BATTEN read notes of a case of Subacute Combined Degeneration of the Cord in association with Pernicious Anæmia. The case was that of a man, aged 45 years, who some five or six years previously—i.e., in 1894—noticed that he was becoming pale. In 1897 he was admitted to the North-West London Hospital, under the care of Dr. Harry Campbell, with pernicious anæmia. He improved under treatment and was discharged. In November, 1899, he was admitted to Regent's Park Hospital, under the care of Dr. L. G. Guthrie, suffering with spastic paraplegia, which had developed gradually two months before admission. He remained in that hospital till February, 1900. He was admitted to "Friedenheim" under the care of Dr. P. J. F. Lush in April of the same year. He had then the aspect of a man with pernicious anæmia; the legs were rigid and there was still slight voluntary power, the knee-jerks were exaggerated, and ankle clonus was present. The examination of the blood showed extreme diminution in the number of red cells, nucleated red corpuscles, macrocytes, microcytes, and poikilocytosis. There was loss of sensation over the feet and legs below the knees. There was complete loss of control over the sphincters and a bed-sore formed over the sacrum. The patient died at the end of April. The microscopical examination of the cord showed degeneration of the posterior columns, degeneration in the region of the crossed pyramidal and direct cerebellar tracts, and also in the region of the direct pyramidal tracts. The liver gave the free cross reaction but not to a marked degree. The pathology of the condition was next dealt with and it was suggested that the cord changes and the anæmia were probably due to one and the same poison. The occurrence of spinal cord changes in association with profound anæmia was well recognised, but only a small proportion of these cases showed changes in the blood characteristic of pernicious anæmia. Dana had stated that proportion to be 10 per cent. The paper was illustrated by lantern slides and microscopical specimens.—Dr. J. A. ORMEROD mentioned the case of a man with symptoms of pernicious anæmia who subsequently developed symptoms pointing to spinal disease—numbness, loss of knee-jerk, &c.—who rapidly sank and died, when changes were found characteristic of this form of disease.—Dr. PERCY KIDD asked what were the precise clinical symptoms in these cases, adding that he had had several cases of pernicious anæmia associated with numbness, and he referred to the case of a man in whom, in addition to numbness and tingling, the knee-jerk was absent. He asked whether this was usual.—Dr. NEWTON PITT asked Dr. Batten whether he had met with cases of the kind in which the changes were limited to the posterior columns. In a similar case under his own observation nothing during life pointed to spinal disease, and he raised the question whether the cases in which the predominant symptoms were those of pernicious anæmia were those in which the mischief was limited to the posterior columns.—The PRESIDENT asked whether any changes had been noticed in other parts of the nervous system.—Dr. BATTEN, in reply, said that the brain was perfectly healthy as far down as the middle region of the pons, where a few degenerated fibres were found in the pyramidal tracts. He regretted that the colour index of the hæmoglobin had not been noted. In regard to the clinical symptoms the loss of knee-jerk was very characteristic. The disease had three stages, one in which there were ataxia with slight spasticity and slight subjective signs, numbness, and tingling in the hands and feet; a second period when the spasticity was marked and the knee-jerk was active; and a third characterised by absolute flaccidity, often coming on suddenly with a rise of temperature, total absence of reflexes, ultimately involving the trunk. It was worthy of note that in spite of the absence of knee-jerk and clonus the Babinski extensor sign could be obtained. In reply to Dr. Pitt he observed that if the pernicious anæmia proved fatal before the disease had advanced very far the changes might be limited to the posterior columns, and he asked whether the case referred to by Dr. Pitt had been examined by the Marchi method, which showed changes of recent supervention. Many cases published by continental observers had apparently had no spinal symptoms and had shown the degeneration limited to the posterior columns.

Dr. CHARLES W. CHAPMAN read a paper on a case of Aortic Regurgitation probably due to Syphilis. The patient was a married woman, aged 40 years, who had been under his care at the National Hospital for Diseases of the Heart. The family history was exceptionally good and the personal history was equally so up to the patient's first confinement at 22 years of age. Out of eight children born at term two died at two years from diphtheria, another had snuffles and died from bronchitis a few weeks after birth. There were four miscarriages from the eighth to the twelfth week. The patient was very feeble and had a wan appearance. On examination the heart's action was found to be unequal; the apex was just under the sixth rib and just outside the nipple line. The cardiac dulness was but little increased. A faint but distinct double murmur was heard in the aortic area. The other organs were healthy. The pulse was feeble. Syphilitic disease of the aortic valve was diagnosed and the treatment consisted of a course of mercury followed by iodide of sodium. Eleven months after treatment the heart sounds were found to be quite normal and had remained so. Thirteen months after the patient had been under treatment an exceptionally healthy child was born who had remained strong up to the present time. He justified his diagnosis by the history of the case and the success of the treatment. He quoted from the writings of Sir William Broadbent, Dr. Clifford Allbutt, and Professor Dieulafoy in support of his contention, and emphasised the importance of recognising syphilitic affections of the viscera by a reference to Wilks' and Moxon's lectures.—The PRESIDENT asked whether there was any notable change in the left ventricle.—Dr. PHILLIPS said it was generally recognised that aortic regurgitation was often the result of syphilis and referred to the case of a young man, an outpatient at St. Mary's Hospital, who had an aortic diastolic murmur and very severe attacks of angina pectoris. He had had syphilis and rheumatism and he improved under iodide of potassium, which, he observed, relieved not only syphilitic but also other cases of angina Some time later the man died, having commissioned his mother to communicate with him (Dr. Phillips) and to ask that his body might be examined. Post mortem they found attached to the aorta a round gumma almost as large as a cobnut. There was hardly any degeneration of the aorta.—Dr. CHAPMAN, in reply to the PRESIDENT, said that the left ventricle was enlarged downwards but not upwards.

Dr. HUGH THURSFIELD read notes of a case of Rheumatic Periostitis with Subcutaneous Nodules. The patient, a boy, aged nine years, was brought to the Hospital for Sick Children in November, 1900, with a marked periosteal thickening of the inner aspect of the shaft of the right tibia and covered from head to feet with subcutaneous nodules. There was no evidence of congenital or acquired syphilis and there were several minor manifestations of rheumatic infection, stiffness, and pain in the hamstring muscles, and a small effusion into the knee-joint. The heart was very slightly dilated, but there was at no time any endocardial murmur. Rheumatic periostitis of the ulna had been recorded in 1889 by Dr. Archibald Garrod and Dr. J. A. Coutts, but was apparently a very rare condition. The appearance of nodules in any number without endocarditis or pericarditis was very rare; in fact, Dr. W. B. Cheadle regarded nodules in any number as certain evidence of severe cardiac lesions. Dr. W. B. Hadden had, however, reported one case to the Clinical Society in 1889, and there could be no doubt that they did sometimes occur, but as a general statement Dr. Cheadle's rule held good.—Dr. A. F. VOELCKER quite agreed that cases in which nodules existed were those in which grave cardiac mischief occurred. In the case of Dr. Hadden's to which Dr. Thursfield had alluded the boy had subsequently been re-admitted with a fresh attack of rheumatism and definite endocarditis.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF MEDICINE.

Paracentesis Thoracis.—Complication of Nerve Diseases.—Friedreich's Ataxia.—Calcium Chloride.

A MEETING of this section was held on Dec. 14th, Sir C. J. NIXON, the President, being in the chair.

Dr. JOSEPH O'CARROLL exhibited a man, aged 65 years, admitted into hospital on May 25th, 1900, for dyspnœa, epigastric pain thirst, frequent micturition, and want of sleep due to dyspnœa. There was a soft systolic murmur at the cardiac apex; the urine showed a faint trace of albumin and some sugar, both by Fehling's test and fermentation. The man went to bed for about three hours in the evening, but could not lie down; he got up about midnight and spent the rest of the night dozing in his chair. A month after admission the right pleura was tapped; in a few days the left, and so turn about. His thorax had been tapped 18 times and a total of 67 pints of serous fluid had been withdrawn. He had not been tapped since Oct. 30th. He had now no dyspnœa, slept well on either side, and could take a little exercise in the hospital garden. The sugar in the urine was never higher than 5 per cent. and it had frequently disappeared altogether. The quantity of urine had averaged about 30 ounces, so that the case was hardly one of diabetes mellitus. Dr. O'Carroll thought the best diagnosis to be mitral disease with subacute dilatation of the heart, which had been cured or relieved by rest.

Dr. JOSEPH O'CARROLL also exhibited a man, aged 50 years, who fell head downwards over a balustrade whilst drunk. In a couple of days he was able to resume his occupation as a greengrocer. Three months later he came under treatment for weakness in his legs and arms. He presented increased knee-jerks, ankle clonus, and Babinski's toe phenomena; simple anæsthesia to touch over the legs and the trunk below the level of the nipples; a soft glossy-skinned aspect of the hands, with some simple anæsthesia and a slightly marked "clawing"; he was also markedly ataxic. The symptoms suggested a transverse myelitis at or about the level of the sixth and seventh cervical roots, but there had been no interference whatsoever with the rectal or vesical functions and at no time had there been any acute paraplegic symptoms.

Dr. TRAVERS SMITH exhibited an unmarried female, aged 24 years, suffering from Friedreich's Ataxia. As far as she could trace her family she knew of no other instance of the disease. She was healthy up to the age of 14 years. She then began to suffer from "nervousness," "trembling," and "staggering," and these symptoms became worse till at the age of 22 years she became unable to walk without a person on each side to support her.

Dr. NINIAN FALKINER said that calcium chloride was of great use in many cases of gastric ulcer, particularly in the relief of pain, and described the increased excretion of calcium compounds in the urine of a person who was taking six grammes of calcium chloride daily.—Dr. WALTER SMITH said that of the total calcium ingesta about 5 or 6 per cent. was excreted by the urine, leaving the rest to other channels, principally the bowel.

BOMBAY MEDICAL AND PHYSICAL SOCIETY.

Sunstroke.—Gangrene of the Tongue.—Suprapubic Lithotomy.—Ovariotomy.

A MEETING of this society was held at the University on Nov. 30th, 1900, Lieutenant-Colonel W. K. HATCH, I.M.S., Vice-President, being in the chair.

Captain J. B. SMITH, I.M.S., described a case of Sunstroke occurring as a complication in convalescence from pneumonia. The case was reported, not from any peculiarity in the pneumonia or in the sunstroke, but because sunstroke must be a very rare complication of pneumonia. The patient was a Mussulman police-constable, aged 19 years, who was admitted to the Civil Hospital, Shikarpur, on June 17th, 1894, with lobar pneumonia of the right lower lobe. The pneumonia was not severe and was unattended with rusty sputa. On June 26th, when he had been convalescent for several days, he went out and exposed himself to the sun, going to the privy, he said. At 4 P.M. he was noticed by his comrades to be "sleeping heavily," and the hospital assistant found that he was unconscious. On Captain Smith's arrival his temperature was 108·8° F. in the armpit, his skin was dry and pungent, and his eyes were congested. There was no new development of the pneumonia, Captain Smith therefore concluded that it was heat-stroke and had him rolled up in a wet sheet, which was constantly wetted and fanned by relays of men. An ice-bag was put to his head, to the back of his neck, and a lump of ice into his rectum. The temperature soon fell to normal, but it rose again when the wet sheet was discontinued. The sheet was therefore re-applied and kept on all night and next day until consciousness returned. Consciousness returned gradually and was not fully restored until 1 P.M. on June 27th—namely, about 21 hours after his illness was noticed. His temperature was slightly raised for several days afterwards. On August 1st he was discharged without the least trace of any ill-effect.

Lieutenant-Colonel HATCH reported a case of Gangrene of the Tongue. The patient was a woman, 45 years of age, who was admitted into the Jamsetjee Jejeebhoy Hospital on Nov 12th. Three months previously a swelling appeared on the dorsum of the tongue and gradually increased in size; for the last month there had been a serous and purulent discharge. The woman was very emaciated and quite unable to walk without assistance. Her mouth was slightly open and emitted a most fœtid odour; the surface of the tongue was of a dirty-brown colour and quite soft, so that a probe could be pushed deeply into its substance without causing pain. The gangrenous portion was removed and the surface was rubbed with nitric acid freely, but the patient gradually sank.

Lieutenant-Colonel HATCH also reported an operation for Vesical Calculus. The patient, a man aged 50 years, from Sholapur, had felt symptoms for two years. The original intention was to crush the stone, but it was found impossible to introduce a lithotrite owing to extreme rigidity about the neck of the bladder. Suprapubic lithotomy was therefore performed and the bladder was sutured, a drainage-tube being passed into it by the perineum. The calculi weighed 17·5 ounces.

Captain A. HOOTON, I.M.S., reported Four Ovariotomies performed on Hindu patients in the Sassoon Hospital, Poona, from December, 1898, to March, 1900. All made good recoveries. Chloroform was the anæsthetic employed. Silk sutures and ligatures were used, as silkworm gut or sufficiently thick silver wire was not obtainable at the time. In one case a buried continuous silk suture caused suppuration with considerable burrowing of pus.—Major W. H. BURKE said that he had known buried silk to give trouble as late as a year after insertion.

HUNTERIAN SOCIETY.—An ordinary meeting of this society was held on Dec. 12th, 1900, Dr. Newton Pitt being in the chair.—Dr. Hingston Fox read a paper on Recovery from Acute Disease: Notes on Prognosis. Diseases were divided into two classes, benign and malignant, according to their natural terminations. In benign diseases recovery depended on keeping the patient alive long enough, and this in the last resort upon the power of assimilating food. Some disorders were malignant because of the bad reaction of the subject—e.g., catarrhal pneumonia in a feeble person. Others were essentially malignant, like acute generalised tuberculosis. An outline was given of cases of fatal progressive pyrexial disease of ill-defined nature in which pneumonia or neuritis or dermatitis were developed. The chief clinical features of a case of acute disorder were then reviewed in the light of prognosis. Inheritance, the common habits of a family, had its influence. The patient's history might show alcoholism or other weakening causes. Sir Andrew Clark laid down that no healthy adult under 40 years of age ought to die from acute specific disease. Stoutness was an adverse factor. So was fear, especially in heart disease, whilst hope and an easy mind were much in favour of recovery. An entirely hopeless prognosis should scarcely ever be given. Illustration was offered of the force of will-power in recovery and the value of sleep. The presence of hysteria or of catamenial disturbance in women was of favourable augury. Blood conditions received some notice, especially the lividity that heralded convulsions; also the bearing of slow and quick heart-rate. Cheyne-Stokes respiration was not necessarily a fatal sign. Appetite and digestive power were important, but patients sometimes died with a clean

tongue. Free action by the primæ viæ and by the skin and kidneys was of good import; a dry skin was evil. Old practitioners acquired an intuitive prognosis apart from reasoning; the younger men were apt to think too much of the physical signs and too little of the patient. As Dr. H. G. Sutton used to say, they must "trust the human body."—Dr. F. J. Smith congratulated Dr. Fox on his paper. He agreed with him as to the gravity of a gradually increasing pulse-rate. He believed that frequent feeding in acute disease was bad and that prognosis was favourable when the patient desired food and had a clean tongue.—Dr. Fortescue Fox referred to cases of obscure pyrexial attacks to elderly people ending fatally. He agreed that the value of feeding acute cases according to the desires of the patient was often great.—Mr. Hope Grant said that there were cases in which the tongue could not become furred because of the absence of filiform papillæ.—Dr. Milligan referred to a child who suffered from chronic hyperpyrexia after an acute catarrhal pneumonia which lasted four weeks. The child eventually got quite well.—Dr. Newton Pitt pointed out that the appearance of a child was a very valuable item in prognosis and that the value of the pulse-rate varied with sex and age.—Dr. Fox replied.

BRITISH LARYNGOLOGICAL, RHINOLOGICAL, AND OTOLOGICAL ASSOCIATION.—The annual general meeting of this society was held at the rooms of the Medical Society, 11, Chandos-street, W., on Jan. 11th.—Mr. Lennox Browne and Dr. Kelson showed cases of Exostosis of the External Meatus; Dr. Abercrombie showed a case of Hyperostosis; and the President showed a case of Exostosis of the Tympanic Cavity.—In the discussion which followed operation was deprecated unless the growth were such as to lead to the accumulation of cerumen, &c., incapable of removal.—Dr. Banks, Dr. Dundas Grant, Dr. P. Jakins, Dr. Vinrace, Dr. Scatliffe, and Dr. V. H. W. Wingrave spoke.—Dr. Wingrave and Dr. F. J. Tresilian showed cases of Facial Palsy due to Middle-ear Disease.—Dr. Culver James showed a case of Middle-ear Disease with Complications.—The President showed a case of Epithelioma of the Maxillary Antrum and Excision of the Upper Jaw. Both specimen and patient were shown. The growth had been completely removed. There was no difficulty in swallowing and no sign of recurrence.—Dr. Banks, Dr. Wingrave, and Dr. Grant discussed the case.—Dr. Grant showed a case of Cyst of the Epiglottis.—Dr. Banks, Dr. Kelson, and the President related similar cases and discussed the treatment.—Mr. W. J. C. Nourse showed a case of Tertiary Syphilis with a Sequestrum in the Naso-pharynx.—Dr. Grant and the President discussed the case.—The President showed a case of Aphonia in a soldier, aged 23 years. The patient, who was in South Africa, took part in a long march, was said to have become unconscious and to have remained so for three days, and had been completely aphonic now for some months.—Dr. Tresilian showed a case of Osteo-sarcoma of the Maxillary Antrum.—The postponed discussion on Dr. Lennox Browne's cases of Epilepsy in relation to Adenoid Growths followed.—The President, Dr. Grant, and Dr. Banks related cases in which improvement had taken place after the removal of adenoids.

CARDIFF MEDICAL SOCIETY.—The ordinary monthly meeting of this society was held at the society's rooms on Jan 11th, Dr. R. Prichard being in the chair.—Dr. Barnardo showed a case of Polypoid Disease of the Right Antrum of Highmore. The patient was a woman, aged 35 years, who had suffered from dry throat and periodical headaches, and pus was seen to be running down the posterior nares. Since the operation of draining the antrum through the canine fossa and nose the symptoms had been much alleviated, but the shadow test showed continued opacity of the antrum.—Dr. Prichard, Mr. J. J. E. Biggs, and Mr. Lynn Thomas commented upon the case and Dr. Barnardo replied.—Dr. Owen Rhys showed (for Dr. C. T. Vachell) an advanced case of Pseudo-hypertrophic Muscular Paralysis in a boy, aged 12 years.—Mr. William Sheen read a paper on the Immediate Investigation and Treatment of Bullet- and Shell-Wounds. The paper was based on six months' experience as surgeon to the Yeomanry Field Hospital. A description of the Mauser wound immediately after infliction was given and the points to be investigated were indicated. The various types of shell-wound were described; and finally the results of certain rarer forms of injuries, such as those caused by expanding bullets and exploding cartridges, were detailed.—A discussion followed in which Mr. Lynn Thomas and Dr. Rhys Griffiths took part, and Mr. Sheen replied.—The President proposed and Dr. D. R. Paterson seconded the following motion:—

That this society congratulates its honorary secretaries, Mr. Lynn Thomas and Mr. William Sheen, on the eminent services they have rendered to their country during the war and rejoices at their safe return home.

The resolution was carried unanimously and the secretaries suitably replied.

LIVERPOOL MEDICAL INSTITUTION.—At the annual meeting of this institution, held on Jan. 10th, the following list of office-bearers and members of council was adopted:—President: Mr. Edgar A. Browne. Vice-Presidents: Dr. T. R. Bradshaw, Mr. W. Thelwall Thomas, Dr. Edward Adam, and Dr. J. M. Hunt. Honorary treasurer: Mr. Henry Briggs. Honorary general secretary: Dr. J. R. Logan. Honorary secretary to ordinary meetings: Dr. John E. Gemmell. Honorary librarian: Dr. H. Leslie Roberts. Council: Dr. James Armstrong, Dr. W. Macfie Campbell, Mr. W. T. Clegg, Dr. J. C. M. Given, Dr. A. M. Paterson, Mr. Andrew Stewart, Dr. James Barr, Dr. R. J. M. Buchanan, Dr. A. Craigmile, Dr. William Macvie, Mr. Edward Nicholson, and Dr. J. Lloyd Roberts. Pathological and Microscopical Committee: Dr. J. H. Abram, Dr. F. H. Barendt, Dr. Rubert Boyce, Mr. R. A. Bickersteth, Dr. R. J. M. Buchanan, Dr. A. W. Campbell, Dr. C. Macalister, Mr. G. P. Newbolt, Dr. C. S. Sherrington, and Dr. W. B. Warrington. Journal Committee: Dr. F. H. Barendt, Mr. F. C. Larkin, Mr. G. P. Newbolt, Dr. A. M. Paterson, Dr. W. Permewan, Mr. W. Thelwall Thomas, Dr. Arthur Wallace, and the honorary secretaries to the ordinary meetings and pathological section.

GLASGOW PATHOLOGICAL AND CLINICAL SOCIETY.—A meeting of this society was held on Jan. 14th, Dr. Alexander Robertson, in the absence of the President, being in the chair.—Dr. Alexander Napier showed (1) three patients, a sister and two brothers, the subjects of Hypertrophic Cirrhosis of the Liver accompanied by splenic enlargement; and (2) a girl, aged six years, who had recovered from Jacksonian Epilepsy under the use of iodide of potassium.—Dr. Finlayson gave a bibliographical demonstration on Physiognomy with special reference to the physiognomy of disease.—Dr. A. Ernest Maylard showed (1) a specimen of Prolapse of the Rectum removed from a woman, aged 54 years, by the method of Mickulicz; and (2) a portion of Jejunum resected from a man, aged 25 years, who had been crushed between two lorries. The bowel was the seat of a circular rupture and the patient had succumbed to peritonitis which had commenced prior to operation.—Dr. E. Arthur Gibson showed (1) Interstitial and (2) Subcutaneous Myomata of the Uterus removed by hysterectomy.

BRISTOL MEDICO-CHIRURGICAL SOCIETY.—The fourth meeting of the session of this society was held in the Medical Library of University College on Jan. 9th, Dr. D. S. Davies being in the chair.—Dr. Patrick Manson, C.M.G., F.R.S., gave a most interesting demonstration of the Life-history of the Malaria Parasite and illustrated it by numerous microscopic preparations, lantern slides, diagrams, and blackboard drawings.—Upwards of 120 members and visitors were present.—At the close of the meeting a hearty vote of thanks to Dr. Manson was carried with applause.

THE LATE MR. A. W. SHEPERD.—Mr. Albert Wilberforce Sheperd died at his residence, Cowbridge, Glamorganshire, on Jan. 4th, after a short illness. The deceased received his medical education at the Carmichael College, Dublin, and took the qualifications of L.R.C.P., L.R.C.S., and L.M. Irel., in 1883. After holding a resident appointment at the City of Dublin Hospital, he was appointed district medical officer at Moriani, Assam, India. On his return to England about 10 years ago he practised at Cowbridge, where he was medical officer of health of the Cowbridge Urban District. The deceased took a great interest in the volunteer movement and was surgeon-captain to the 2nd Volunteer Battalion of the Royal Welsh Regiment. Mr. Sheperd was highly esteemed and very popular in Cowbridge, and much sympathy is felt there for his widow and two young children.

Reviews and Notices of Books.

La Vie de Pasteur. RENÉ VALLERY-RADOT. Paris: Libraire Hachette et Cie. 1900. Pp. 692.

"L'ŒUVRE de Pasteur est admirable, elle montre son génie, mais il faut avoir vécu dans son intimité pour connaître toute la bonté de son cœur." These words were written by Dr. Roux, Pasteur's colleague and friend. They are quoted on the title-page of "La Vie de Pasteur" and give very suggestively an idea of the spirit in which the book has been written by M. René Vallery-Radot, the son-in-law of the subject of the biography.

The first impression received on reading the book is a hope that it will soon be translated into English so that it may be more readily accessible to the English people, but on reflection it becomes evident that a good translation would be almost impossible. A mere transliteration, a turning of French words into English equivalents more or less exact, would give no just idea of the work and might easily prove absurd; it would necessarily destroy much of the charm of the book, which consists largely in the brief and touching sketches it contains of the domestic life of Pasteur and of his most intimate personal friends. Here and there glimpses are given of that happy and united family life which is probably not uncommon amongst French people, but the details of which are so carefully guarded that they are rarely seen by foreigners, and very rarely by Englishmen, who, proud of "home," often profess to pity a people who have no such word and do not appreciate the significance of the association which a Frenchman has with "famille." The associations of family ran like a golden thread all through the life of Pasteur. One other thing also greatly affected him, as it did all his thoughtful fellow countrymen—the great national catastrophe of 1870. The pitiable condition of France under the foreign invader made the iron to enter into his soul. He became for a time unable to continue his scientific researches and cast about for a solution to the problem as to why France had not found in her hour of need men fit to cope with her difficulties. In the pamphlet which he wrote on this question he ascribed the lack of really great men to the neglect that the country had shown to those who devoted themselves to scientific work. At the end of the eighteenth century, he argued, the country in her time of stress had been saved by her men of science. They had taught how the saltpetre necessary for the manufacture of gunpowder could be obtained by methods hitherto unknown, and by what new processes cannon could be quickly manufactured and how offensive arms could be rapidly provided. Napoleon himself felt the power and the use of applied science and after the battle of Waterloo proposed to go to America to devote himself to such work. Napoleon III., on the contrary, had neglected science, and on one occasion Pasteur wrote with extreme warmth on the action of the Government in this respect, a point to which reference will be made later. The strong impression produced on Pasteur by the disaster of 1870 was shown by the way in which he returned to the University of Bonn a degree which had been conferred on him. It was shown by the fact that towards the end of his life he declined to entertain the idea of receiving a German Order. It was shown by the depth of his gratitude and the greatness of his surprise at the reception which he met with in England as the foremost representative of France at the International Medical Congress of 1881, when at the opening meeting held in St. James's Hall he was greeted with the warmest enthusiasm. On this visit he met the German Crown Prince, and he appreciated the graceful tact of Sir James Paget in not asking him to be presented to the prince, and also the way in which that noble-minded gentleman introduced himself to Pasteur and addressed to him the few words of friendliness and peace which he recorded in a home letter written at the time and which he ever afterwards remembered. Patriotism and family affection were amongst the strongest characteristics of Pasteur, and these qualities may possibly be ascribed in part to heredity.

Jean-Joseph Pasteur, the father of the subject of this biography, was a man of strong character. Born in 1792, he became a conscript in 1811, and fought in Spain during the two following years; he returned to France in 1814, and in that year the regiment in which he served (3rd Infantry) distinguished itself at Bar-sur-Aube and Pasteur became a sergeant-major and received the Cross of the Legion of Honour. After the abdication of the Emperor in 1814 he obtained his discharge from the service and returned to Salines, where the Royalist mayor ordered the "Brigands of the Loire"—as he called the soldiers of the Empire—to give up their swords. Pasteur obeyed, but when he found his sword in the possession of a policeman he wrested it from him. Some trouble followed, but the commander of the Austrian forces, which still held the town, sympathised with Pasteur, who was not afterwards interfered with. An "old soldier" although but 25 years of age he settled down to the business of a tanner, and across the stream—miscalled la Furieuse—he soon found his fate in the form of a young gardener who worked there from early dawn. It was Jeanne Etienne Roqui. She came of a family well known in the town and could trace her descent from a vine-grower who lived in the middle of the sixteenth century. The members of her family had the reputation of being so much attached to one another that "to love like the Roqui" had become proverbial. These young people were married in 1815 and in 1822 a son, Louis Pasteur, was born. He received the early part of his education at Arbois. The Pasteur family had amongst their acquaintances several men of some culture who took an interest in the young student. Amongst these was Dumont, a retired army surgeon, on whose advice young Pasteur was sent to Paris to continue his studies. He was then only 16 years of age and the great city terrified him. He became so homesick that his father brought him back for a time; he afterwards went to Besançon, where he took the degree of *bachelier ès lettres* in the year 1840. At the examination he did not greatly distinguish himself; he pleased the examiners in Latin, in Greek, and in rhetoric, but did only moderately well in history and geography. After leaving Besançon he went to Dijon, and in the examination for *baccalauréat* in sciences and mathematics he came out fourteenth in the list of 22 candidates. He was "weak" in chemistry. In 1842 Pasteur returned to Paris, where he attended lectures at the Lycée Saint-Louis and those of Dumas, the chemist, at the Sorbonne. He worked very hard, suffered from headache, and lived with great frugality. His father gave him some very good advice, counselling him to dine well at least twice a week with his great friend Chappuis and adding that he had bottled some 1834 wine which should be kept for their return. There was, he said, more spirit in that wine than in all the books of philosophy which had ever been written, but he cautiously added that it would not help to solve mathematical formulæ.

The companionship of Chappuis was a great help to Pasteur. Left to himself he devoted all his time to study and was constantly in the library. With his friend he discussed during their walks those problems which interested him, and his ideas became clear when he examined them from different points of view. The first great problem which he wished to solve had reference to a mystery about tartaric acid and its conduct with polarised light, and from this inquiry he hoped to be enabled to get a general insight into the relation between crystalline form and the polarisation of light. It was a great work and the results which he

obtained startled Biot, the great chemist, who immediately saw the possibilities of scientific advance which Pasteur's discovery had made possible. For 30 years Biot had worked at the subject, and now at the age of 74 he found that this student of 25 had made a discovery which would revolutionise chemistry. Although incredulous at first, Biot repeated Pasteur's experiments, proved their results, and recognised their importance. He welcomed the discovery with a large-hearted sympathy and ever after he was Pasteur's most devoted friend.

In 1849 the professorship of chemistry at Strasburg was offered to Pasteur. He accepted the appointment but felt lonely. He immediately fell in love with a daughter of M. Laurent, the principal of the University, and proposed for her hand a fortnight after he first saw her. They were soon married. Fortunately his wife was willing that his work should continue to occupy most of his time and of his energy.

The family party at Strasburg was, unluckily, soon broken up. In the year 1850 the clerical party became for a time dominant in France and Romieu was appointed to visit the universities. M. Laurent fell under his dipleasure and was removed. Pasteur remained. In 1852 he undertook quite a romantic quest in search of crude specimens of tartaric acid. Never, as a contemporary writer said, was treasure, never was beauty more ardently sought. The conditions under which racemic acid had been produced were not understood and Pasteur journeyed to Leipsic, Freiburg, Vienna, and Prague to procure specimens which had been obtained under different conditions. His letters to his wife contained accounts of his journey and ultimately he was able to send a telegram to Biot to say that he had converted tartaric acid into racemic acid So at length Pasteur established the existence of the four tartaric acids: (1) which turned the plane of polarised light to the right; (2) which turned the plane of polarised light to the left; (3) the combination of the two (or racemic acid); and (4) which was inactive to light. This was a great discovery and one not obtained by accident but as the result of carefully devised experiment. In recognition of these researches Pasteur received the Ribband of the Legion of Honour. In the autumn of 1857 he was made professor of the newly-established Faculty of Sciences at Lille. This appointment marked a distinct epoch in the scientific life of Pasteur. Until then all his researches had been suggested by his own brain, the problems were those set to him by himself. From this time the problems were thrust upon him. The great town of Lille was a manufacturing centre and the production of alcohol from the fermentation of beetroot was an important industry of the place. Some of the manufacturers had been much troubled with a difficulty in the process of their operations and they were quite unable to account for it. One of them sought the advice of Pasteur, and thus he began the study of fermentation. The *savants* had hitherto considered fermentation to be a strange and obscure process. The theories of Berzelius and of Liebig were generally accepted. But they explained nothing. Fermentation was supposed by one of these philosophers to be due to the action of contact, "catalytic influence"; according to the other it was due to the presence of a "ferment," a readily decomposable organic substance. So the theories may be briefly put. Pasteur showed that the formation of alcohol from sugar was due to the vital action of living organisms, that the changes were produced by organised cells.

From 1860 to 1864 Pasteur was engaged chiefly in investigating the question of spontaneous generation, but he spent some time also in studying the diseases of wines. Biot and Dumas both thought that the inquiry as to the possibility of spontaneous generation was a barren subject—an insoluble problem and therefore not one on which time should be spent. But the question was one which it was impossible for Pasteur to neglect. The problem, he thought, must be settled. It stayed the progress of science. The *savants* were lost in a valley. Biot said there was no way out. Pasteur found it necessary to try to find one. And Pouchet of Rouen had claimed that he had proved the occurrence of spontaneous generation. This was too much for Pasteur. He began a new study—that of the microscopic organisms of the air. It was a long business and took him far afield, for he investigated the mountain air of Chamounix. It was a fierce fight between the *savants*. It is needless to go over the battle ground.

In 1864 the Mayor of Arbois asked Pasteur to investigate the cause of the trouble which the vine-growers had experienced in keeping their wines. Facilities for the investigation were offered, but Pasteur declined to accept the generosity of the town and made his own arrangements for the research. The trouble was a very real one and had far-reaching results, for the English market was becoming closed to wines which were liable to ready decomposition. Pasteur came to the conclusion that the wines were spoiled by a secondary fermentation and that this source of danger could be eliminated by raising the wine for a short time to a suitable temperature.

The next great undertaking of Pasteur was an investigation of the disease of silkworms which threatened entirely to ruin the silk industry and had already caused a loss of something like £4,000,000. Pasteur felt great diffidence in undertaking the task which was assigned to him. He had never touched a silkworm and knew nothing about their culture. The literature of the subject he found of little use to him, and on going to Alais to study the disease on the spot he found, as might be expected, that it was difficult to find any definite fact in the deluge of words which was poured into his ears. But all sorts of remedies were recommended and the word "miasm" was much to the fore. Pasteur studied the silkworms microscopically and obtained some healthy eggs from Japan that he might compare healthy worms with those which suffered from the disease. His work for a time was interrupted by the death of his father, but he soon returned to continue his investigation; and he was able to show that the disease was the result of a microscopic organism and also that eggs derived from a healthy source produced worms free from the disease.

Pasteur's next work was literary. He edited Lavoisier's works at the urgent request of Dumas. The book was much praised by Sainte-Beuve. Soon after this Pasteur spent a few days at Compiègne at the command of Napoleon III whose guest he became. This visit must have been one of great interest both to the host and to Pasteur. To Pasteur the sight of an Imperial hunt must have been quite a new sensation. But he was not satisfied to do without work. The Imperial cellar contained a few—very few—bottles of wine which had "gone wrong" and he was pleased at the opportunity afforded him of finding out how this had come about. The Empress was also greatly interested in the objects seen under the microscope and a drawing-room lecture was given at her five o'clock tea. It was a matter of wonder both to Napoleon and to the Empress that Pasteur had made no attempt to obtain a "legitimate profit" from the commercial application of his labours, but he told them that in France the *savants* did not think it seemly to act in such a way. But the researches of Pasteur in regard to the disease of silkworms is said to have been the means of saving to France an amount of money equal to that which was paid to Germany as part of the price of peace.

Pasteur was a man possessing the strongest human sympathy and the greatest kindness of heart. A remarkable instance of the display of these qualities was shown by the action he took when he heard that his old friend Claude Bernard had retired into the country overwhelmed with dyspepsia and suffering from great mental depression.

Pasteur, hoping to be able to raise his spirits, devoted himself to a renewed study of his works and wrote an article for the *Moniteur Universelle* ("Claude Bernard: Idée de l'importance de ses travaux, de son enseignement et de sa méthode"). The article had the happiest effect, Bernard's condition immediately improved; he was filled with gratitude and was soon well enough to return to his work.

At the Great Exhibition at Paris in 1867 the grand prix was awarded to Pasteur and to 62 others; the prize-giving ceremony was one of the most imposing scenes amongst those of the Second Empire. Gérôme, Meissonier, and Ferdinand de Lesseps were present and received due honour. Art and industrial progress received greater acclamation than that accorded to science. At this period the laboratories were ill-placed and unsuitable for their purpose. Situated in cellars, they were not unfitly described as the "tombs of the *savants*." Pasteur, moved by these facts, addressed a note to the Emperor pointing out the industrial value of the investigations which he himself had carried out and showing what a vast and fertile field for further research had been discovered by his researches. A full investigation of the phenomena of putrefaction and for the study of infectious diseases necessitated spacious and isolated laboratories. The pathology of gangrene and experiments in inoculation could only be studied in specially constructed places. The transport of butcher's meat had a distinctly commercial aspect. In Europe it was sold at an exorbitant price, in Buenos Ayres it was only too plentiful. It was a point worthy of experiment to see whether it was possible to invent some method for its transport. Pasteur was led to hope that laboratories would be built by the Government, but he was disappointed. Whereupon he wrote a very strong article. The article was naturally refused by the official *Moniteur*, but it appeared first in the *Revue des cours scientifiques* and afterwards in the form of a pamphlet. It had an immediate effect and the Emperor took up the question warmly. The following year Pasteur had a severe illness which was diagnosed as cerebral hæmorrhage. He was then only 46 years of age, but for a time it appeared as if his work were over, and he grieved that there was so much left for him to do. The general impression evidently was that the new laboratory, which was then in the course of construction, would not be wanted, and Pasteur, on asking his wife how the building was getting on, was grieved to hear that the work had been suspended. When the Emperor was told of this he ordered that the work should be continued at once. Later, when Pasteur was recovering from his illness, Napoleon III. placed at his disposal the Villa Vicentina, a house near Trieste which had once belonged to Elisa, sister of Napoleon I., by whom it had been left to her daughter, Princess Baccischi, from whom the Prince Imperial inherited it. At the Villa Vicentina Pasteur superintended the culture of silkworms, which had failed miserably before his advent. Just before the fall of the Empire Napoleon had placed him in the list of new senators, but the decree was never issued.

Of the effect of the war on Pasteur mention has already been made. The unnecessary injury done by the Germans to the Sèvres porcelain factory and the destruction of the manuscripts there amongst other things violently affected him. His search for his son, who was serving in Bourbaki's army, was a romance, but it is not possible to tell the story here.

The fact that Pasteur after his attack of cerebral hæmorrhage was able to do excellent work is very remarkable. Much of the work of his later years was that which attracted most the attention of foreigners. After the war he was engaged for a time in the investigation of the manufacture of beer, which had not up to that time been a favourite beverage with his countrymen. At a later period he was elected to the Académie de Médecine. Physicians and surgeons alike had learned much from his researches. Lister founded on them a new system of dressing wounds which in a few years revolutionised surgery, was the means of saving thousands of lives, and for the first time made it reasonable to undertake operations which had previously been carried out only by the most "enterprising" surgeons to the great risk of the lives of their patients. Both Lister and Tyndall gladly acclaimed the greatness of the results of the teaching of Pasteur. Some of the French physicians, it is true, rather disliked Pasteur's intrusion into their domain, but his teaching has survived any prejudice which it may have excited.

In the year 1880 Pasteur began a series of experiments in regard to chicken cholera and to the attenuation of its virus, and at a later date he undertook those investigations concerning hydrophobia which perhaps of all his work caused the greatest immediate popular sensation. The details of this work and of the origin and work of the Pasteur Institute are so familiar that it is not necessary to do more than mention them.

Pasteur continued to work till November, 1894, when the symptoms of his mortal illness manifested themselves, but he lived until the following September, when he breathed his last surrounded by his family and by his friends.

It is not possible to give in a review any adequate idea of the interest of M. René Vallery-Radot's book. The subject of the biography was one of the greatest men of the century in which he lived, and the book has been written from ample material and with loving care. It is well worthy of careful study. To the casual reader and for purposes of reference a good index would have been a great boon. A complete bibliography of the published works of Pasteur should also have been added to the book. These omissions it is to be hoped will be made good in future editions of the work.

Somnambulismus und Spiritismus. (*Somnambulism and Spiritualism.*) By L. LOEWENFELD. Wiesbaden: J. F. Bergmann. 1900. Super royal 8vo, pp. 57. With two illustrations.

THIS little book is the first of a series of pamphlets edited by Dr. Loewenfeld of Munich and Dr. Kurella of Breslau which is addressed to "the educated of all classes" and in which questions relating to the borderland between the spiritual and material existences are to be discussed. While there is a certain fascination about most borderlands, the one with which the volume before us is concerned is particularly interesting because it is here that the lands which science has already explored march with a region which has only recently begun to be investigated. We refer to the somnambulistic state, a term which in the somewhat wide sense in which the author uses it includes the hypnotic condition and certain phases of hysteria. Dr. Loewenfeld does not define somnambulism, but we gather that he regards it as a condition in which the area of mental activity is narrowed in some directions but extended in others—that is to say, a condition in which some of the senses are asleep while others are in a state of hyperæsthesia. Consciousness, apparently, may be partially or wholly in abeyance. Though the author believes that the most familiar form of somnambulism—ordinary sleep-walking—indicates a morbid state of the nervous system, he does not think it is to be regarded as an early symptom of hysteria. He demolishes the popular belief in the miraculous powers exhibited in that condition and concludes from his own observations that the sleep-walker does nothing in sleep which he could not do awake were his faculties concentrated to the same degree on the work in hand.

Of the hysterical variety Dr. Loewenfeld has little to say. It is responsible, he believes, for some of the cases of

so-called dual existence of which Azam's case of Felida X. is one of the most remarkable.

The author's principal contention is that in hypnotic somnambulism is to be found an explanation of most of the manifestations of spiritualism. To the abnormally sensitive ear of the hypnotised subject, for example, sounds are audible which cannot be detected by the bystander, such as the "involuntary whispering" by which thoughts are "read"; his brain is sensible to impressions (as in telepathy) to which it is impervious in his waking moments. In short, while we do not know all the channels by which these impressions are conveyed nor the means by which they are produced Dr. Loewenfeld feels justified in attributing to the abnormal acuteness of the somnambulist's senses much that the spiritualist ascribes to supernatural agencies. Table-turning and rappings he lightly dismisses as hocus-pocus; the phenomena which he discusses seriously are telepathy, clairvoyance, the power of seeing through opaque substances, that of talking in a language unknown to the speaker, and the transposition of senses. He does not think that the last two have been proved to have occurred; and with regard to the third, he would also declare himself an unbeliever were it not for one or two of Richet's experiments, the results of which were so striking that he is compelled to admit that they could not be due to chance. As to telepathy and clairvoyance, he unwillingly admits their existence, holding that while most so-called examples are due to deception or coincidence, there are some which cannot be thus accounted for—which are, indeed, in the present state of our knowledge inexplicable. We cannot quite understand the evident reluctance with which the author makes these admissions. It seems to arise from a fear that they may be regarded in some sort as a concession to his spiritualistic opponents against whom this work is chiefly directed. The value of the book is considerably impaired by this unscientific attitude which allows him to be more alive to the weak points in the spiritualistic arguments than to those of his own theory. These fears are quite superfluous, for while waiting for a rational explanation we are not compelled, even provisionally, to accept the one which the spiritualist proposes. The book is a very interesting introduction to an important subject.

Mosquitos and Malaria: A Summary of Knowledge on the Subject Up-to-Date; with an Account of the Natural History of Some Mosquitos. By CUTHBERT CHRISTY, M.B., C.M. Edin., Special Medical Officer on Plague Duty for the Indian Government; late Senior Medical Officer, West African Frontier Force, Nigeria. With five full-page Plates. London: Sampson Low, Marston and Company, Limited. Bombay: The *Times of India* Press. 1900. Demy 8vo, pp. xii–80. Price 6*s.* net.

THE researches of Grassi, an Italian naturalist, and the experiments of Bignami, subsequently to the publication of Ross's papers showing that special mosquitoes were needed as the hosts of the malarial parasites, succeeded in affording positive evidence of the inoculation of malaria by mosquito bites, and this result was confirmed by the experiments of Bastianelli, Grassi, and others. The Royal Society has also issued a series of reports into the origin and character of malaria, embodying information gained on both coasts of Africa—West and East—which are of considerable scientific and practical value.

The subject of the connexion between the prevalence of mosquitoes and the prevalence of malaria which is dealt with in this volume has been so frequently referred to and discussed in the pages of THE LANCET and elsewhere that we may fairly assume our readers to be acquainted with the general results, at any rate, of the numerous investigations which have been taking place. These researches make up one of the most interesting and important chapters in the history of modern scientific medicine. Nor is their interest circumscribed within the limits of medical science only, for the subject also offers an interesting field of study to the naturalist and the microscopist, and, in its practical bearings in connexion with public health, it more especially concerns the statesmen and population of the British empire. Notwithstanding that malarious diseases are so prevalent in India and in some of our possessions abroad, it is the Italian school of medicine which laboured longest and most persistently in the study of malaria—indeed, in this respect it has long held a foremost position. Since Laveran's discovery of the malarial parasite in 1880 the subject has been pursued on all sides with keen interest. This took a fresh start at the time that Major Ronald Ross, I.M.S., by a series of skilful and carefully conducted observations gave precision to the mosquito-malarial theory of causation, which had been previously and provisionally elaborated in 1893 by King in America. Since that time, as our readers are aware, there has been a rapid and progressive advance in our knowledge.

The introductory chapter on the Malarial Parasite and that on Ross's discoveries in 1897–98, followed by an account of Dr. C. W. Daniels's investigations in Calcutta in 1899 and of the work of the Italians are very clearly and succinctly written. At the stage at which Dr. Daniels undertook his inquiries and wrote his report, he was able to say that Ross's discoveries had put observers on the high road to proving that the mosquito conveyed malarial fever from man to man, although they did not prove that it was the only way in which the fever could be carried. Since Daniels wrote his report, however, much has happened. Dr. Christy deals very clearly and well with the natural history of mosquitoes in general and with all that is known about our particular enemy—the genus anopheles. Beyond the recognised four stages of development—viz., that of the egg, the larva stage, the pupa or nympha stage (all of which are passed in water) and the fourth or adult winged stage, there is much that still remains to be known about the natural history of mosquitoes. It is a more intimate knowledge of the life-history of the mosquito, and especially of the anopheles, in all the four stages that is required, and the author calls the attention of observers to some of the main points needing further elucidation. The chief aim which Dr. Christy had in view in publishing his little work was, he states, to stimulate the interest and to enlist the energies of naturalists, medical men, and others throughout the world. At pages 39 and 40 he gives a very useful table of comparison between the culex and anopheles. In the succeeding chapters he treats of the methods of destruction of mosquitoes and the etiology of malaria and its prophylaxis. The series of plates with their accompanying brief explanatory notes are excellent.

The object of the present work, its author tells us, is to supply, in the form of a small cheap handbook, a concise and convenient summary of our knowledge—the literature of which would, if it were all collected together, make up a little library in itself. The author has performed his task excellently well and if his volume does not include everything known and published up to the present moment, that is simply attributable, as we have said, to the rapid progress which is being made.

Gynæcological Operations, Exclusive of those Interfering with the Peritoneal Cavity. By SKENE KEITH, M.B., F.R.C.S. Edin. Illustrated with 44 figures. Edinburgh and London: Young J. Pentland. 1900. 8vo. Pp. 118.

THIS little book is intended as a companion to the author's "Text-book of Abdominal Surgery." It contains a good and concise description of the essential details of the gynæcological operations usually performed through the vagina. Mr. Skene Keith enters a protest against the excessive preparatory measures which at the present time are considered essential by many operators even before the most

trivial operations. No doubt in the private practice of surgeons many of the elaborate precautions usually taken may be neglected, but in hospital practice, where the operator is dependent to some extent upon others, it is essential that the minutest details should be observed, so that carelessness in slight matters may not lead to carelessness in great matters. It is, moreover, only by the jealous care that a modern surgeon takes over his antiseptic or aseptic precautions, as the case may be, that he is able to inculcate these important principles upon his students and so to endow them with the most important attribute of a good surgeon, "the antiseptic or aseptic conscience." The descriptions of the various operations abound in practical details, and are in many instances more clearly and graphically described than in most text-books. The author prefers a Sims's speculum and Sims's position, a fact that must be borne in mind by those who are more accustomed to the dorsal position, in reading the account of the operations.

The practice of drawing down the uterus to the vulva is condemned, but we must confess that although we are in the habit of drawing down the uterus in the majority of cases when operating upon it through the vagina we have yet to meet with the rise of temperature and evidence of pelvic inflammation which the author says are often the result of this manœuvre. It seems to us more likely that such unfavourable results are due to the operation performed rather than the method. Mr. Keith fails to note the greatest danger—viz., the possibility of rupturing a pyosalpinx or a small ovarian cyst if the uterus be drawn down without a careful preliminary bimanual examination in all cases. We are glad to see that the old-fashioned method of plugging the vagina with a kite tail is rightly condemned. The practice of plugging the interior of the uterus after the operation of curettage appears to be an unnecessary complication in an ordinary case, while the application of pressure forceps to the pedicle of a fibroid polypus is a superfluous precaution in our experience. We see no reason why a large Bartholin's cyst should not be cleanly dissected out as well as a small one, and what we have seen of the method recommended by the author—viz., incision of the cyst and the use of scissors—in the hands of other surgeons would not lead us to adopt the plan. Although we cannot quite agree with all the author says, yet the book is well worth reading by those interested in gynæcological surgery, and will prove of much assistance to the inexperienced in such operations.

The Great Famine and its Causes. By VAUGHAN NASH. With Eight Photographs by the Author, and a Map of India showing the famine area. London, New York and Bombay: Longmans, Green, and Co. 1900. Pp. 262. Price 6*s*.

THIS volume consists of the series of letters which originally appeared in the *Manchester Guardian* during the 11 weeks which Mr. Vaughan Nash spent in India. He must have occupied himself with untiring energy to have travelled and witnessed all that he did in that distressed country, and to have gleaned and compiled all the information which he has managed to set forth in this volume. The letters describe with a good deal of graphic force the scenes which the author witnessed as the panorama of suffering unfolded itself, together with the impressions to which they gave rise. Their perusal is necessarily a sad and painful experience. The history of India of recent years has been a terrible record—one of plague, pestilence, and famine. The native population is enormous and for the most part sunk in poverty at the best of times, and more largely dependent even than the population of other countries upon the regularity and normality of its meteorology—i.e., upon the recurrence of its seasons in due course—for its food-supplies. When, as occasionally happened in the history of the late famine, the ravages of cholera are superadded to those of famine, and starving crowds of enfeebled people have had to leave relief works and camps and seek safety in flight for fear of being stricken with a more rapid and dire disaster than that of famine, it is not easy to conjure up a more terrible picture. The author has a good deal to say about such subjects as Indian organisation, how India is fed, famine preventive measures, debt and expropriation, and the land revenue system, some of which matter is interesting. But these are affairs of State policy and government about which our readers must consult the book for themselves, for they do not readily lend themselves to any brief analysis, nor do they fall within the purview of the medical critic. But we may remark that the views of anyone founded upon a brief residence in India with a relatively cursory experience and necessarily inadequate consideration of such big subjects are mainly intended for the information and enlightenment of readers in this country. Whether they happen to be right or wrong they are not likely to carry any great weight with the Indian Government and its officials.

Consumption: its Nature and Treatment. By WILLIAM H. SPENCER, M.A., M.D. Cantab., M.R.C.P. Lond. London: Henry J. Glaisher. 1900. Pp. 83. Price 1*s*. 6*d*.

DR. SPENCER'S temperate views on the nature of consumption are explained in this little brochure. He lays it down that the bacillus plays only a secondary part in the determination of the disease. The depraved tissue habits which provide the suitable conditions for its growth operate in the same direction as the agent which finally compasses the ruin. The only certain method of destroying the bacillus within the body is to deny it the conditions which are essential to its development. And it is with the various methods of withholding these conditions that the author chiefly concerns himself in these pages. In addition to ordinary hygienic measures, curative and prophylactic, Dr. Spencer has great faith in the efficacy of the so-called antiseptic inhalations, not for the purpose of directly destroying the bacillus, but of indirectly effecting this object by rendering the animal matter on which it thrives an unsuitable nutritive medium. The reader is not, however, supplied with the details of treatment.

LIBRARY TABLE.

Messieurs Vigot Frères of Paris send us a little book by M. de Frumerie, entitled *La Pratique du Massage*. It is a collection of clinical lectures on instruction in massage given to the classes of hospital attendants, both male and female, of the Paris hospitals during 1899–1900. The book is an octavo volume of 146 pages, contains 31 figures and diagrams, and costs two francs. Commencing with a short historical synopsis of the art of massage the author passes on to give a description of the different manipulations, and continues by giving an account of the physiology of the muscles and a description of massage of the different parts of the body. There is also a chapter on massage of recent fractures. Of course no one can learn massage purely from a book, but M. de Frumerie's instructions will prove of value to anybody who is desirous of learning something about massage before he enters on his practical class.

From Messieurs G. Carré and C. Naud of Paris we have received a book by M. H. Triboulet, physician to the hospitals, and M. F. Mathieu, physician to the Bureaux de Bienfaisance. The title of the book is *L'Alcool et L'Alcoolisme*, in one volume, square octavo, with 254 pages, and the price is 5 francs. The preface states that the book does not pretend to be more than a compendium for the use of those who know of facts connected with the alcohol question. Certain phases of the question have been more dwelt upon than

others, such as the manufacture of alcoholic drinks in their relation to drunkenness, the toxicology of alcohol, and the general physiology of the matter. The mental pathology of alcoholic poisoning is not dealt with. The first chapter gives an account of the word "alcohol" both in its restricted meaning as implying ethylic alcohol and in its wider chemical meaning of a series of alcohols. Then follows an account of the various alcoholic drinks such as beers, wines, ardent spirits, liqueurs, and *apéritifs*, including absinthe. Chapters on the toxicology and physiological effects of fermented drinks follow and then the authors pass to consider the pathology of alcoholic intoxication. This chapter concludes with a section on treatment, both therapeutic and moral. Statistics of the consumption of alcohol in different states are next given, and the book concludes with a succinct account of the various prophylactic measures for combating alcohol in different countries and a scheme of prophylaxis drawn up by the authors. For a book of no great size this little work contains a vast amount of information upon a subject which is possibly of more vital importance to the health and growth of nations than any other. M. Triboulet and M. Mathieu's suggestions are well worth pondering upon. Shortly, they propose: 1. Special legislation which, however, must be backed up by private effort. All alcohol should be taxed except that employed in industries. 2. Taxes on coffee, cocoa, and tea should be reduced as much as possible. All profits accruing from the taxation of alcohol should be employed in works of charity. 3. No alcoholic drinks should be allowed to be sold in barracks, arsenals, or railway works. 4. In large towns public-houses should be closed at 11 P.M., except those near theatres and railway-stations, while in small towns and villages they should be closed at 9 P.M. in winter and in summer six hours before sunrise. 5. No person under 18 years of age and no drunken person should be served. All establishments where drinks are sold should be compelled to be well ventilated. Civil legislation should provide establishments for the treatment of the habitual drunkard, and the State should only allot its posts of employment among members of temperance societies; while owners of property should be made to see that the houses for which they receive rent are in a proper sanitary condition. M. Triboulet and M. Mathieu allow that the problem is far from easy to solve, but they maintain that their system is worth trying.

Encyclopédie Scientifique des Aide-Mémoire.—Under the above heading Messieurs Masson et Cie., the Paris publishers, are issuing a series of handbooks to various departments of medicine and the kindred sciences. We have before us three of the volumes, which are octavo books, price 2 fr. 50 c. each. The first, *Maladies des Voies Urinaires*, by M. Bazy, surgeon to the Beaujon Hospital, deals with the general and symptomatic therapeutics of these diseases and with the operative surgery which is sometimes necessary for the relief of diseased conditions of the urinary organs. Two volumes have already appeared of this series, the first dealing with exploratory operations and those of urgency, while the second deals with symptomatology. The volume under review is the third, and a fourth, upon special therapeutics, will complete the series. The present volume is divided into three parts. In the first M. Bazy treats of the various drugs which affect the urinary organs and secretion. Next he passes to the consideration of special therapeutics and treatment, such as that of hæmaturia, urinary infection, and urinary insufficiency, together with the treatment of retention. In the final portion of the book a description of various operations upon the urinary organs is given. The book is very clearly and simply written and though, of course, it, as well as the whole series, presupposes knowledge on the part of him who consults it, it should be found to be, as the name suggests, a valuable refresher of the memory. The second volume before us is entitled *Analyse Biologique des Eaux Potables*, by Dr. J. Gasser. There is but little doubt that the purity of the water-supply is one of the most, if not the most, important factors in the health of a community. Beginning with an account of the apparatus necessary for bacteriological examination Dr. Gasser proceeds to give an account of the methods of estimating the microbes present in a given sample of water and concludes with a description of the pathogenic organisms carried by water as well as the more common organisms which exist in water, such as bacillus ramosus. The third volume before us bears the title *L'Insuffisance Hépatique* and is by Dr. A. Gouget, physician to the hospitals. It deals in a plain manner with the signs, symptoms, causes, and treatment of the condition called by Murchison "lithæmia." As a *résumé* of a very common and yet complex condition, one, moreover, which is by no means easy always to treat successfully, this little book may be recommended.

Über die Ursache des Alters: Grundzüge der Physiologie des Wachsthums mit besonderer Berücksichtigung des Menschen. (The Determining Causes of Age: Elements of the Physiology of Growth, with especial Reference to the Human Subject.) By Dr. M. MÜHLMANN. Wiesbaden: J. F. Bergmann. Glasgow: F. Bauermeister. 1900. Pp. 195. Price 5 marks.—Dr. Mühlmann has for several years been making observations on the weights of different parts of the human body and the study of these data has led him to several interesting conclusions. He finds, for instance, that an investigation and comparison of the phenomena of growth in the several components of the body are far more instructive than mere weighing of the entire body. It is customary to reckon three principal stages or epochs of human life—namely, (1) the period of growth extending from birth to 25 years of age; (2) the period of maturity extending from 25 to 40 or 50 years of age, during which growth ceases and a condition of equilibrium is maintained; and (3) the period of old age which immediately follows that of maturity. The leading features of an individual life may be summarised in this way, but the study of the growth of separate organs or parts of the body casts quite a fresh light on the subject, revealing the fact that each organ has its own stages of youth, maturity, and old age, and that in none of the organs does this series of changes take place coincidently in point of time with the corresponding changes which affect the body as a whole. The body attains its greatest size during the third decade and continues about the same during the fourth and fifth decades. The brain, however, attains its greatest size in the second decade, the kidneys in the third, the muscles, skeleton, intestines, and liver in the fifth, and the heart and lungs in the eighth decade—i.e., in extreme old age. Increase or decrease in the weight of the body is therefore not due to simultaneous increase or decrease in the weight of all its component parts, but is the resultant of an increase in some organs and a decrease in others. The brain attains its greatest weight about the fifteenth year of life, and as the ratio of its weight to that of the whole body is at the highest in the new-born infant its growth relatively to that of the body evidently diminishes from birth onwards. The liver and kidneys present analogous conditions but in a much less marked degree. The loss of weight which is one of the features of old age is chiefly due to wasting of the bones and muscles. In the last two chapters of his work Dr. Mühlmann treats of metabolism at different periods of life and discusses the pathological changes of old age, comparing them with the effects produced by chronic starvation in middle life.

Studien über die Ursachen der Lungenkrankheiten. (*Considerations relative to the Causes of Diseases of the Lungs.*) By Dr. N. PH. TENDELOO. Part I. (Physiological). Wiesbaden: J. F. Bergmann. Glasgow: F. Bauermeister. 1901. Pp. 118. Price 3 marks 60 pfennig.—As is well known, some diseases of the lungs have a marked tendency to localise themselves in certain portions of these organs. Starting from this fact Dr. Tendeloo of Rotterdam, formerly assistant in the Boerhaave Laboratory at Leyden, set himself to study the question whether the changes in volume produced in the pulmonary vesicles during the act of respiration were the same in all parts of the lung. Both physiological and pathological methods are obviously calculated to throw light on the subject, and in the present treatise Dr. Tendeloo deals with the physiological part, reserving his pathological inquiries for a second work to be published at an early date. The conclusions which he has so far arrived at are as follows:—1. The changes in volume produced in the pulmonary vesicles during the act of respiration are not the same in different parts of the lungs. They are least in the paravertebral supra-thoracic portions and from this point they increase in all directions at varying rates, attaining their maximum in the caudal lateral portions. In every part of the lung and in each lobe of it the changes in volume produced in the pulmonary vesicles during the act of respiration are greater in the periphery than in the centre. 2. The renewal of the air is proportional to the magnitude of the changes in volume produced during the act of respiration. 3. The average kinetic energy of the air in motion is during one and the same phase of respiration directly proportional in the different parts of the lungs to the respiratory changes in volume. 4. The average amount of blood and probably also the average amount of lymph present is least in the supra-thoracic portions of the lungs but increases gradually in the caudal direction. 5. The kinetic energy of the lymph current during expiration is, on the whole, proportional to the respiratory changes of volume.

Hong-Kong: Report of the Principal Civil Medical Officer for 1899. By J. M. ATKINSON, M.B. Lond., D.P.H. Cantab. Pp. 38.—In his report for 1899 Dr. Atkinson states that the estimated population of the colony at that time was 259,310. There were 1132 births and 6181 deaths, 1434 of the latter being from plague. The birth-rate was 4·3 per 1000. The general death-rate was 23·8 per 1000; excluding the deaths from plague it would have been 18·3 per 1000. The death-rates according to nationalities were as follows: whites, 12·5 per 1000; Indians and coloured persons, 28·3 per 1000; and Chinese, 24·4 per 1000. At the Government Civil Hospital 2734 patients were admitted, of whom 811 were "Europeans," 659 were "Indians and coloured persons," and 1264 were "Asiatics (Japanese included)." Among the appendices there is a report by Dr. J. A. Lowson showing that at the Tung Wah Hospital 2542 patients were admitted; of this number 1491 were treated by the Chinese native doctors, 556 were under western treatment, and 495 (chiefly plague patients) were transferred to other hospitals. At the Infectious Hospitals, Kennedy Town, 37 cases of small-pox and 226 of plague were admitted. The average strength of the troops serving in Hong-Kong during 1899 was 1643 white and 1325 black; the average daily rate of sickness was 186·4 among the whites and 64·9 among the blacks. The mortality per 1000 of the strength was 11·5 among the whites and 7·5 among the blacks. The highest mean monthly temperature was 83° F. in July; the highest monthly rainfall was 20 inches in August.

To the Passion Play and Back. By J. JOHNSTON, M.D.Edin. Bolton: Tillotson and Son, Limited. 1900.—In this little pamphlet of 40 pages Dr. Johnston gives an account of a holiday excursion made with a friend to Ober Ammergau to witness the Passion Play. He gives a simply written description of the almost solitary mystery play which exists at the present day and his words give a good idea of the remarkable effect which the realism, the devotion and the reverence of the performance produce. The Passion Play, as is well known, had its origin in a vow made by the villagers in thankfulness for deliverence from a destructive epidemic which ravaged the country over 200 years ago.

JOURNALS AND MAGAZINES.

Edinburgh Medical Journal.—The opening article in the January number is the first of Dr. G. W. Balfour's Morison Lectures on Insanity, delivered before the Royal College of Physicians of Edinburgh. Under the general title of "The Borderland" he has collected a variety of instances in which persons subject to mental abnormality or disorder have attained great distinction in philosophy and science, as military and religious leaders, and in literature, his representative examples being Socrates, van Helmont, Joan of Arc, Mohammed, Dean Swift, William Cowper, and Christopher Smart. Professor Chiene of Edinburgh University publishes an account of his experiences with the medical department of the army in the South African war; in concluding he expresses the hope that the medical history of this war will be fully described in the same form and with the same thoroughness as the great civil war in America has been dealt with by the Government of the United States. In a presidential address delivered before the Edinburgh Obstetrical Society Dr. R. Milne Murray directs attention to the increasing puerperal mortality in private practice as contrasted with the very low death-rate in lying-in hospitals. Mr. W. Arbuthnot Lane writes on the operative procedures in simple fractures which have been unscientifically treated.

Scottish Medical and Surgical Journal.—The first article of the January number is devoted to the Scottish National Red Cross Hospital at Kroonstad, Orange River Colony, the author being Mr. Henry E. Clark, senior surgeon to the Glasgow Royal Infirmary. The first contingent of the hospital left Glasgow on April 20th, 1900, and arrived at Kroonstad on May 25th. Another member of the staff of the same hospital, Dr. Robert Stirling, surgeon to the Royal Infirmary, Perth, writes on the war establishment of the R.A.M.C. He considers that "the augmentation of the R.A.M.C. through civilians and civil hospitals does not supply that homogeneity and elasticity essential to the needs of a great war." In his opinion the best plan would be to form a large reserve of officers and men annually mobilised in military hospitals and paid during such periods of training. Dr. J. M. Cowan, physician to the Scottish Branch Red Cross Hospital, contributes a short article on the outbreak of enteric fever at Bloemfontein and the results of inoculation with Professor Wright's prophylactic.

Caledonian Medical Journal.—In the January number Dr. Alastair MacGregor of Shepley, Huddersfield, continues his articles on second sight, relating a variety of fulfilled premonitions of death; among the persons who experienced these premonitions were Dr. MacGregor's mother and brother, the present Lord Charles Beresford, and three Yorkshire clergymen. A considerable number of Gaelic anatomical terms are introduced in the course of a review of Mr. Alexander Carmichael's "Carmina Gadelica." Some space is devoted to announcements relative to the Gunning Celtic prizes of the Caledonian Medical Society which have been already mentioned in THE LANCET of Dec. 8th (p. 1658) and Dec. 22nd (p. 1825), 1900. The essays for which these prizes will be given must be sent to the secretary, Dr. S. R. Macphail of Rowditch, Derby, by Jan. 1st, 1902.

Mercy and Truth.—The January number contains articles on a medical mission in the north-west frontier of India by Dr. W. B. Heywood, and on medical work in Mombasa by Mr. C. S. Edwards.

THE LANCET.

LONDON: SATURDAY, JANUARY 19, 1901.

The Royal Commission on the Beer-poisoning Epidemic.

THE recent epidemics of peripheral neuritis, the discovery of arsenic in beer, and the possibility of arsenic being contained in any other food-stuffs, are among the points which have been referred for elucidation to a Royal Commission the constitution of which we print elsewhere. The terms of reference of the Commission are so wide that it is practically certain that this decision of the Government will lead to no prompt legislation, however urgently there may be need of it. Great public questions have, of course, in the past become clearer under the macroscopic and microscopic examination of a Royal Commission. And where such questions have involved an enormous mass of evidence being taken before any clear position could be defined or any definite line of action could be mapped out, delay in rendering a report and hesitation on the part of the Government in taking consequent action are inevitable. The case of the beer-poisoning epidemic, it seems to us, is very different, since there is plenty of evidence at hand, and this evidence is of a very unmistakeable kind, freely supplied by scientific men and business men anxious to tell the truth. Unless the scope of inquiry at present outlined for the Commission is not materially reduced, enabling it to do its work in less than a month, we think it a pity that it was appointed, for there is, in our opinion, an abundance of facts and material at hand which would have enabled the matter to be adequately and fairly discussed in Parliament without awaiting more information. Practically every instruction on the agenda presented to the Commissioners has been to some extent satisfied by the evidence of competent scientific men, for the economical aspect of the use of substitutes is not referred to the Commission. We are glad that the subject is to be approached in the first instance from the health point of view in order that an ugly stigma on our health administration may be removed once and for all and that the purity of our food-supply may be placed beyond reproach.

A Royal Commission is usually a long while in issuing a report because of the great crowd of witnesses that are enlisted to give evidence before it. Rapid action for the public and the sake of all concerned in the various calamities is what is required in the matter under consideration. If a Royal Commission must needs be held to make investigations respecting the beer-poisoning epidemic it is earnestly to be hoped that it will limit its interrogations to those important witnesses who have at their disposal the facts. The first instruction on the agenda before the Commissioners is "to ascertain with respect to England and Wales the amount of recent exceptional sickness and death attributable to poisoning by arsenic." The reports contained in our columns and in those of our contemporaries, medical and lay, show that fresh cases are occurring nearly every day, and therefore it will not be possible to gauge the true extent of the epidemic for some time. A good idea, however, of its area and of its distribution and of the number of individuals whom it has affected has already been given in the reports of the medical officers of health of the districts concerned, and again the number of cases admitted at hospitals are recorded and the deaths attributable to poisoning by arsenic in beer are of course registered. The second instruction on the agenda relates to "whether such exceptional sickness and death have been due to arsenic in beer or in other articles of food or drink, and if so (*a*) to what extent; (*b*) by what ingredients or in what manner the arsenic was conveyed; and (*c*) in what way any such ingredients became arsenicated." If we omit the words "other articles of food or drink" we shall be perfectly right in saying that the evidence already gained upon the point as to whether such exceptional sickness and death have been due to arsenic in beer is conclusive. The suggestion that the investigation should include other articles of food or drink besides beer opens up an enormous field for inquiry which will delay more than anything else the extinction of the mischief and the prevention of its recurrence. We honestly believe that unless the scope of inquiry, for the present at any rate, be confined to the beer-poisoning epidemic the appointment of a Royal Commission will be valueless so far as regards a speedy relief of the present unsatisfactory condition of affairs. In taking this view we find that we are in complete accord with the attitude of Mr. CHAPLIN, whose word on the subject of Commissions, whether Royal or Departmental, is well worth attention, for it is well known that he can claim an enormous experience. Referring to the second instruction to the Commission he writes to the *Times* "that he does not hesitate to say that with a reference so wide that it extends to all other articles of food and drink in England which are numbered by the hundred a Commission may easily sit for any time from five to seven or more years." Further, as Mr. CHAPLIN points out, the question of food and drink has only recently been legislated upon afresh after a very long inquiry by a Treasury Committee. He alludes obviously to the Food and Drugs Act of 1899 which provides against the presence of deleterious substances in foods, drugs, and drink.

We feel that the Government have already an ample supply of facts at hand in order to give the question fair discussion with the view to the introduction of a short Bill to prevent arsenic poisoning by means of beer. We care not whether such a Bill is directed to the interdiction of malt substitutes or whether it forbids the sale of all food and drinks except under their proper name, so long as it meets with an urgent requirement of public health. We do not suppose for a moment that Parliament will ever decide that only a certain fluid of a certain composition may be legally called beer, or will commit itself to any narrowly protective measure, but without doing either of these things the introduction of arsenic into beer can be stopped. The last instruction to the Commission provides that "if it is found that exceptional sickness and death have been due to arsenic

in beer or in any articles of food or drink to ascertain by what safeguards the introduction of arsenic therein can be prevented." There need be no "if"; exceptional sickness and death have been traced indubitably to arsenic in beer. Why, then, await the report of a Royal Commission to interdict by law the recurrence of such tragedies? We doubt the expediency, or even necessity, of this Royal Commission. It is an excellently composed body, but we cannot help feeling that it is being asked to answer questions that no longer need be put, and to suggest remedies which could be applied without its intervention.

The Modern Treatment of Stone in the Bladder.

BEFORE the time of CHESELDEN many and various methods of lithotomy were practised. Most of these were forms of perineal lithotomy, though they were crude and unscientific, but on a few occasions the suprapubic operation was practised. The introduction by CHESELDEN of the lateral operation of lithotomy early in the seventeenth century led almost at once to the discarding of all the various other methods which had previously been employed for the removal of stone from the bladder, and its pre-eminence was not seriously attacked for nearly 200 years. In 1822 CIVIALE placed on a firm foundation the operation of lithotrity and the value of the crushing operation was rapidly recognised and its employment spread widely. Yet there was no real tendency for lithotrity in the form then employed to displace the lateral operation of lithotomy, and it may be said that lithotomy remained the chief operation for vesical calculus for 50 years after the introduction of lithotrity, the crushing operation being performed in those cases only which were considered to be especially suited for it. And no material change was made in surgical procedure under lithotrity until the year 1878. The operation was still performed in several "sittings," and the crushed fragments were still removed mainly by the natural urinary flow. BIGELOW, in 1878, published his method of crushing the stone; he employed lithotrites still more powerful than those previously used, crushed all the fragments and removed them at the one operation. BIGELOW showed that this procedure was much more readily tolerated by the bladder than less thorough operations in which many of the fragments were left within the viscus which thus never had the complete rest which was necessary for its recovery. BIGELOW'S new operation was accepted after a little hesitation by all, or nearly all, surgeons throughout the world, and in a very few years the operation with which CIVIALE'S name was associated had died out; and so thoroughly had the later replaced the earlier operation that the name "lithotrity" was transferred to the new operation, and, in fact, at the present time when lithotrity is spoken of BIGELOW'S method is always intended. The name "litholapaxy" is occasionally used to designate the operation introduced by BIGELOW, but it is not unlikely ultimately to be given up for the somewhat shorter if no more euphonious "lithotrity."

About 1880 an attempt was made to re-introduce the "high" or suprapubic form of lithotomy; this was supported chiefly by Professor PETERSON of Kiel and by Sir HENRY THOMPSON. The operation was, of course, not in any way new, as it had been performed at intervals from the middle of the sixteenth century, and in 1875 Dr. C. W. DALLAS collected 465 cases of the operation which had been recorded in medical literature. The mortality from suprapubic lithotomy has varied greatly, but in skilled hands the results in suitable cases are comparable with those of any other method. At present it can only be considered advisable in certain cases in which lithotrity cannot be performed. Though BIGELOW'S operation had replaced all other methods for removal of a vesical calculus in adults, boys were until recently still submitted to the cutting operation, as it was thought that in them the calibre of the urethra was insufficient for the introduction of suitable lithotrites. But in 1884 Dr. D. F. KEEGAN, then a surgeon-major in the Indian Medical Service, published his results on lithotrity in boys, and these showed that the operation was as applicable to boys as to adults and that the mortality after lithotrity was distinctly less than after lithotomy. This teaching has been accepted and lithotrity in boys may be considered to be fully established, though naturally even more than ordinary care has to be employed in the operation. Thus it has come to pass that in all cases of stone in the bladder the crushing operation presents itself as the most suitable means of removal and that a lithotomy should only be performed where some insurmountable obstacle exists to the effective use of the lithotrite.

Much of the work which has lead to these conclusions has been done in India, where there is an unrivalled field for the treatment of stone in the bladder. The frequency of vesical calculus in some parts of that country is very great, and it does not appear strange, when the large population and the comparative scarcity of surgeons are considered, that it sometimes falls to the lot of a surgeon in India to operate in several hundred cases of stone. In an interesting discussion on this subject which was held at the last meeting of the British Medical Association it was maintained by some of the speakers that the stones in India were not of such firm consistence as those met with in East Anglia, and therefore that conclusions based on Indian experience were not applicable to calculi met with in this country. The opposite opinion was strenuously maintained by others at that meeting, and it may well be that though there is some difference in the hardness of these calculi the difference is but slight. A striking indication of the extent to which treatment of stone is required in India is afforded by the appearance recently of a special number of the *Indian Medical Gazette* devoted to the consideration of vesical calculus and its proper therapeutics. In this are printed articles by Dr. KEEGAN and others who have had much experience in this branch of practice and many notes are also given on special points in connexion with lithotrity. No surgeon can doubt after reading our contemporary's special number that at the present time the safest and the most speedy method of removing a stone from the bladder in nearly every case is BIGELOW'S operation of lithotrity.

The Battle of the Clubs at Wigan and Elsewhere.

MUCH has been said lately about the disposition of the friendly societies to act with consideration towards the members of the medical profession, but with every inclination to publish accounts of such a happy state of affairs we have been unable to come across a well-authenticated case. Yet any ungracious attitude on the part of such societies towards the medical profession is ungenerous as well as unjust. Whatever faults may be alleged against the original club system are due to the system itself, which was essentially an inadequate one, the product of old conditions, when the means and position of the working classes were very different from what they are now, and when medical education and equipment were also different. But even under that system, when the working man was poor, when there was little organisation of his order, when he counted for nothing in society and had no political power in the State, the medical man was his most constant friend. And through all the political changes of the last two or three generations it has been the same, the medical man has been on the side of all that made for the amelioration of the position of the poor. Now the working man is well paid; his class is highly organised; he meets his employers on almost equal terms; the labour and the skilled workmanship he has to give are as indispensable to national prosperity as is capital itself. He himself is in a degree educated; his children are more so, and the development of our complicated civilisation has created good places for them, for which they can be fitted by an education for which their parents pay only partially and indirectly. The working man of to-day is of political consequence. And withal he is a good fellow, and in his way, as Lord ROBERTS said of his soldiers, a gentleman. He has achieved his position largely by the genius for organisation which characterises his class. Is it conceivable that he should be offended with medical men for organising too, or for thinking that the petty remuneration with which club practice was rewarded in past days is quite out of place now? We cannot believe that this is the real feeling of the working man, or that if the facts were clearly placed before him it would continue to be so.

Yet what are we to think when we read some accounts of the action of large numbers of working men, acting not in their individual capacity, but as medical aid associations? THE LANCET of last week contains a report of the manner in which certain of the Durham and Northumberland miners, men of integrity who are prosperous, have received the demand of the medical profession for an advance of pay from 6*d*. a fortnight to 9*d*. A large proportion of the miners have refused to grant the advance asked for. An equally instructive story comes from the district of Glasgow, where all workmen are well paid. Dr. J. A. WILSON of Springburn has for 15 years served the Rechabites for 2*s*. 6*d*. a year per member, many similar societies giving 4*s*. or 5*s*. Dr. WILSON appealed for an increase to 4*s*., and asked also that children should be examined before admission to the benefits of the "tent," as the local organisation is termed, and that the pay for attending them should be raised also. The Rechabites, in reply, consented to increase the pay of adult members to only 3*s*. per annum but refused to raise the pay for children to this amount, though they agreed that they should be examined before admission to the "tent." The medical profession generally supported Dr. WILSON, but one medical man—there always seems one in such cases—consented to do the work on the shabby terms of the Rechabites. This week another story of the relations between the friendly societies and the medical profession reaches us through the press, and again we fail to see in it any sign of urbanity on the part of the societies. At Wigan, according to a report in a local paper there has been rejoicing over the formation of the Wigan and District Friendly Societies' Medical Association. This association has been formed in response to the action of the Medical Guild of Wigan which demanded better terms. The members of the new association are said to number nearly 5000. They have taken premises and opened a medical hall with great show of triumph and a resolution to have "a medical officer of their own." Druids and Oddfellows and Foresters dined and rejoiced together and thereafter held a meeting at which they tried hard to justify themselves for scouting the medical profession of Wigan. They appear to have acted under the guidance of Mr. BIBBY, described as "secretary to the Warrington Society." He seems to have been the orator of the evening, and he allowed himself the use of language towards the medical profession of Wigan and of arguments which contrasted with the tone of his audience and the statements of such as spoke. Amongst other things which Mr. BIBBY said was that in the majority of cases the cause which led to the formation of these medical aid associations was "the old club system, or in other words a slightly better form of treatment than paupers usually received." In refutation of this libel we have only to quote the words of the secretary of the Wigan Friendly Societies Medical Association—Mr. CAVEY—who in describing the battle between his association and the medical profession said that they were acting "in no spirit of animosity. They looked upon the services of the doctors in the past as honourable and they had no complaint to make in that respect." Mr. BIBBY added that the Wigan Association (the Medical Guild was obviously meant) had been "simply kicked out. It served them right. They ought to have been kicked out years ago for being so blind to their own interests." In the light of Mr. CAVEY'S words Mr. BIBBY is seen to be a highly inaccurate person, but we will try to believe in spite of his unmannerliness that he more accurately represented the motives of those who form friendly associations when he said that "they did not desire to do anything against the interests of the local doctors, they tried to conform strictly to the recognised rules of medical etiquette, that they did not advertise, they did not canvass, they desired the goodwill of every medical gentleman, and whether they got it or not they would do everything in their power to deserve it." Unfortunately, these are only words; what the medical profession would like to see is some action on the part of the friendly

societies that did not seem directly antagonistic to the profession.

As we understand the situation in Wigan one medical man has been found to do the work of many by attending single-handed on 5000 people. And this event is applauded as a victory over the medical profession by a meeting at which important speakers say that the Wigan friendly societies do not "desire to do anything against the interests of the local doctors" but "desire the goodwill of every medical gentleman." The action of the Wigan friendly societies is not only contrary to their secretary's statement and to the opinions expressed by the leaders of friendly societies in their repeated interviews with the Committee of the General Medical Council, but it has led or is leading up to a piece of sweatin which working men and their unions would be the first to condemn in their own employers. The working men of Wigan, acting as employers, propose to exact an amount of work from one man that should employ three or four, and they will defend their action as sweaters always do by saying that the man they have hired gets what he contracted for. No one man can give proper medical attendance to 5000 people. An authority which the Wigan friendly societies cannot repudiate, that of the Friendly Societies' Medical Alliance, laid down nearly 20 years ago, in 1883, when working men's wages were not so good and medical education was not so long and expensive as now the following order, that "when (medical aid) associations have upwards of 5000 members it will be found that either three medical men or two medical men with a dispenser will be required." It is not the medical profession of Wigan—save, perhaps, one of its members—that has to be ashamed or afraid of an arrangement which commits the health of 5000 persons to the care of one medical man.

Annotations.

"Ne quid nimis."

THE EDUCATION OF CRIPPLED AND FEEBLE-MINDED CHILDREN.

EVER since the publication of the report of the Royal Commission on Blind and Afflicted Persons in 1889 much interest has been shown by the public, and by the medical profession, as to the best methods of providing for the care and education of children who are unable to attend the ordinary schools. Special day classes for cripp'ed and feeble-minded pupils were first instituted by the London School Board; their example was followed by some provincial authorities and the Education Act (Epileptic and Defective Children), 1899, provided special money grants for the education of defective children properly certified. An impetus has thus been given to this useful department of education, which is extending in many directions guided by public effort and private philanthropy. Early last year the Liverpool School Board opened a special institution for the reception of day pupils who are crippled or mentally defective and placed it in the charge of a head mistress and three assistant teachers, with a nurse. At present there are on the register 67 cripples and 49 mentally weak children. Those who cannot walk are conveyed to school in an ambulance or by omnibus. Couches as well as chairs and desks suitable for the cripples are provided. There are also baths in the institution where a nurse is in attendance who can apply simple dressings and attend to the children. The teachers superintend the dinners which are provided in the school, and by their kindness, tact, and patience they have done much to train habits of obedience and quietude in the pupils in place of unrest and the desire to disobey orders, however kindly given, which is so common among such children when they are neglected. The children are kept employed as far as possible through the day, with intervals for rest and play, when they are encouraged to help one another; the child with heart disease can amuse his fellow with spinal curvature who may not move from his couch. Occupations are planned to be of increasing usefulness and interest according to the ability and advancement of the pupils, commencing with bead-threading, cane-weaving, knitting, and advancing to mat-making or needlework. The purpose of each form of occupation is educative and progressive. Music and singing by the tonic-sol-fa system are found useful and promote comradeship and harmony in the school. We are glad to find that much attention is given to the cultivation of speech and the correct sounding of words written on the blackboard, while some pupils are taught arithmetic, grammar, and geography. Common knowledge is not neglected, and the children have learnt something of the heroes of the present war and of its principal events. Genuine success has been achieved. We are told that "recently a man called at the school to express the gratitude of all the people in one thoroughfare on account of the improvement that had been wrought in the conduct of one lad whose parents lived in that street." Much useful work has been done during the eight months that the school has been open. We should like to learn more about the system adopted in training the feeble-minded children in observation and judgment and as to the physical exercises used. The institution is under the medical supervision of Mr. Damer Harrisson who has shown great interest in the welfare of the children and their progress.

THE CERTIFYING OF STILLBORN INFANTS.

A SINGULAR charge against two medical men, Mr. D. T. Jones and Mr. J. M. James, was investigated before the Recorder of Sheffield at the borough quarter sessions on Jan. 11th. The defendants were indicted, the one for wilfully giving a false certificate that a child had been stillborn which had been, in fact, born alive, and the other, his partner, for aiding and abetting him in the same offence. Witnesses were called for the defence, including one of the defendants, and in the result the defendant charged with aiding and abetting was acquitted by the direction of the Recorder, while a similar verdict was also eventually found in favour of the other, coupled with an expression of opinion by the jury that he had been guilty of gross carelessness. From the evidence given on both sides we gather that the child in question was born prematurely, but that as to whether it was born at seven or at six months there seems to have been conflicting testimony; that after its birth Mr. Jones, one of the defendants, arrived and expressed the opinion that it could not possibly live, and took no particular steps to prolong its existence beyond having it placed in a blanket before the fire, while it was not alleged by the prosecution that the life of the child lasted for more than 12 hours after its birth. There was evidence that some attempt was made to feed it with sugar and butter on the finger of a witness, but no steps were taken by anyone to see whether the mother could nurse it. There was also evidence that it uttered sounds, but Mr. Jones declared that it did not do so when he was present,

saying that it made a spasmodic attempt to breathe and that that was the only sign of vitality that it showed while he was present. Leaving out a question raised as to his giving a certificate of its having been born alive and then withdrawing it, the terms of which certificate seem to have been disputed by him, we need only add that he finally certified that it was stillborn, although he is credited with the admission in the report before us that "he did not think it possible that the child had lived 12 hours," as the prosecution asserted, an admission which seems to us on the face of it inconsistent with a certificate that the child was born dead. His defence, however, seems to have been that the child was practically stillborn and that so he was justified in giving the certificate. Mr. T. R. Jessop of Leeds and Dr. Henry J. Campbell, lecturer on medical jurisprudence at the Yorkshire College, Leeds, who were called on behalf of the defendants, supported this view and apparently were of the opinion not only that a child such as they had heard described could not possibly survive—a matter which we have not discussed and which was not seriously questioned at the trial—but that a child in such a state was "practically dead" and that for it to be practically dead justified a certificate that it was stillborn. To determine the precise moment at which life ceases is not always easy, or, indeed, possible, but this is a different thing from contending that a person showing but slight signs of life, which signs admittedly must soon cease, is "practically dead," dead so truly as to justify a certificate that he is dead. Such a point could hardly be argued in the case of a grown person; but can it any more be raised in that of a newly-born infant? Important issues might hang upon the hour named by the medical man testifying to a death. The devolution of property might depend on whether a certain person, whether infant or adult is immaterial, lived long enough to inherit or died an hour or two too soon. In the case of an infant a charge of manslaughter or murder often depends on whether it was stillborn or had separate existence from its mother. In such a case a medical man, who before any charge of a criminal sort was made, had certified a child to be stillborn only because it was "practically" so, might find himself in an awkward predicament. In the case tried at Sheffield there was apparently no evidence given of any motive for the course taken by the defendant who gave the certificate, except some suggestion of a saving of fees to the relatives, and no doubt this want of evidence of motive influenced the jury who censured him for making a mistake and gave him "the benefit of the doubt." It is, however, possible that in such a case the parents of a child might be deeply interested in concealment and in the avoidance of scandal, and that secrecy might to some extent be gained by the stillborn certificate which, though it does not remove the obligation to register, simplifies formalities with regard to burial. In any case, we cannot admit a state of "practical" absence of life justifying a certificate of death or of stillbirth, unless conditions exist consistent with death and with death only, while we regard the accuracy of all certificates of birth and death to be of the utmost importance, whether great issues be involved or not.

SUBPERIOSTEAL FRACTURES.

IN the *Boston Medical and Surgical Journal* of Nov. 29th, 1900, Dr. Frederick J. Cotton calls attention to this comparatively unrecognised condition. Green-stick fractures are, of course, subperiosteal, but the type considered by Dr. Cotton differs from the ordinary green-stick fracture in that there is not a partly-broken bone and a deformity, but a clean-cut crack or transverse fracture and no deformity. Crepitus is absent. Subperiosteal fractures are, according to the writer, common in children but before the introduction of skiagraphy into surgery they escaped notice. The following cases are related. Case 1. A boy, aged 13 years, had his right arm injured in a football scrimmage. Next day he complained of slight pain and weakness in the hand and arm. There was no swelling or ecchymosis. At the middle of the radius there was localised tenderness, but the application of considerable force gave rise to no suspicion of deformity or mobility. The arm was put up in splints and examined at intervals. Not until 10 days after the injury was anything felt. Then a small callus was felt at the point of injury and a skiagram showed a transverse fracture apparently involving the full thickness of the bone. Three weeks after the injury repair seemed to be complete and the arm could be used freely. In Case 2 a fracture ran obliquely across the radius just above the epiphyseal line. A skiagram showed a clean fracture with practically no displacement—a condition corresponding to the not infrequent Colles's fracture without displacement occurring in adults. Case 3. A boy, aged seven years, fell on his elbow. Under ether a fracture running obliquely upwards and outwards was made out. There was no deformity and but little mobility. Case 4. A girl, aged five years, fell on her elbow. Next day there were effusion into the joint, pain, and tenderness. Careful examination showed no sign of fracture, but skiagraphy revealed a distinct crack across the humerus above the epiphyseal line. Case 5. A girl, aged five years, fractured her right clavicle. Disability and pain were slight. The only sign of fracture was the formation of callus. Dr. Cotton performed experiments on the cadavers of newly-born children to see how readily fractures could be produced and how much the periosteum hindered displacement. By slow forcible bending green-stick fractures with intact periosteum of the femur, tibia, and clavicle were produced. The latter could be bent double and back again with some breaking of the bone but no definite fracture line. A humerus was stood on end and struck on the upper end. It broke in the middle. There were some displacement and hinge-like movement, but the periosteum was untorn.

SHAKESPEARE AND MOLIÈRE AS PSYCHOLOGISTS.

M. COQUELIN'S attempted differentiation between Shakespeare and Molière in the current number of the *Grande Revue* contains many admirable points, but the versatile actor would be more than mortal if all were equally accurate. Molière's and Shakespeare's conceptions of life are wholly different, he says in conclusion. Shakespeare saw life as in a dream; he was an artist and nothing more. Molière saw things in their reality. Now, in a preceding passage M. Coquelin, after expatiating liberally on the merits of Shakespeare's women, felt constrained to note as a curious fact amongst them all, whether charming, profound, or sublime, that there is not to be found the equal of an Agnes or of an Armande. "In Shakespeare," exclaims the talented critic, "the chastest young girl has eaten of the tree of knowledge. The ignorance so dear to Arnolphe appears impossible to the English poet. Juliet is only 14, yet she is a woman. And even Miranda—brought up on a desert island with, for sole companions, her father and Caliban, and who in so many respects resembles Agnes—even Miranda has not the innocence of Agnes." To the questions Are such characters as Armande and Agnes true to life? and Is the portraiture of Molière more in accordance with reality than that of Shakespeare? the answers, if based upon the teachings of physiology as well as of psychology, must be in the negative. These young women, who were by no means idiots or fools, had entered upon the

stage of sexual maturity and were therefore aware by personal experience of the physical manifestations which that state entails on their sex. The state which M. Coquelin so strenuously lauds as *innocence* is in reality merely *ignorance*, and instead of deserving laudation calls for pity. Chastity founded and depending on ignorance is not a quality to excite admiration. It is a condition obviously fraught with peril and demanding removal at the proper time by means of judicious instruction. There is nothing to be ashamed of in knowledge, nor does the possession in the smallest degree detract from the exquisite loveliness of purity. On the contrary, it enhances it exceedingly in the eyes of all who are endowed with a true sense of proportion. The poet tells us that

> "Even the lion will turn and flee
> From a maid in the pride of her purity,"

but assuredly he never meant his couplet as an encomium on want of knowledge. The false modesty which desires to enwrap ignorance with the glamour of pseudo-sanctity is dying hard, but happily dying.

ANGINA DUE TO FRIEDLÄNDER'S BACILLUS.

IN the *New York Medical Journal* of Dec. 22nd, 1900, Dr. Emil Mayer has described a form of membranous sore-throat due to the bacillus of Friedländer, an organism found in certain cases of croupous pneumonia and also in other inflammations—stomatitis, rhinitis, membranous bronchitis, dacryocystitis, and ulcer of the cornea. In throat affections this bacillus was first observed by Max Stoss.[1] A woman, aged 30 years, had a sore-throat for eight days with insignificant general symptoms. On the right tonsil there was a white roundish exudation which yielded the bacillus of Friedländer in pure culture. The next cases, five in number, were investigated bacteriologically by M. Nicolle and his pupil M. Hebert,[2] and they form the basis of the latter's Thèse de Paris (1896). These two observers found the bacillus eight times in 1600 cases of sore-throat. W. C. C. Pakes[3] stated that since November, 1894, tubes of serum inoculated from 500 cases of sore-throat among the in- and out-patients of Guy's Hospital yielded the bacillus of Friedländer five times. Twice it was found in pure culture, twice in association with the bacillus diphtheriæ, and once with the staphylococcus aureus. Two more cases have been recorded by Billet.[4] The preceding are all the cases on record which Dr. Mayer could find. The following case came under his observation. A girl, aged 19 years, in good health, had suffered for 18 months from a chronic membranous inflammation of the throat. When untreated the membrane recurred two or three times a week, lasting one or two days and then becoming completely exfoliated, leaving the throat apparently healthy. If removed forcibly a raw surface covered by a glairy material was left. The surface bled on manipulation. The area affected varied; sometimes the entire pharynx and soft palate were covered. The formation of the membrane was accompanied by a sense of tightness in the throat. The membrane at first was very thin and adherent. Scattered through it were numerous small blebs. In a few hours the membrane became thick and pearly white. The suffering then was great. The patient learned to relieve herself by making gashes in the membrane with the point of a pair of scissors. Exfoliation took place without pain, leaving a reddened surface. Examination of cover-slip preparations and cultures never revealed the diphtheria bacillus but always Friedländer's bacillus almost in pure culture. Analysis of all the recorded cases shows the following facts. Angina due to Friedländer's bacillus may be acute or chronic. In the acute form there is on the tonsils and pillars of the fauces whitish-brown or pearly, somewhat adherent, membrane. The subjacent tissue is slightly inflamed. In the chronic form the tonsils, pillars of the fauces, palate, and posterior surface of the pharynx are strewn with white, pearly, or yellow elevations varying from one to five millimetres in diameter. They adhere closely to the mucosa which appears bloody or slightly inflamed. To remove them forceps or curette must be used. They are quickly reproduced, but, unlike diphtheritic spots, they show no tendency to coalesce. Symptoms may be absent or consist only of dryness of the throat, cough, and frequent attempts to swallow. The cervical glands are not swollen. In the acute form there may be some fever, lassitude, and headache. The duration varies from two or three weeks to several months. Dr. Mayer's case differs from those previously recorded in some respects. In but one of the latter was there a continuous membrane; in his case the entire soft palate was covered and the posterior wall of the pharynx had an independent membrane. As to treatment, the acute form tends to spontaneous cure. In the writer's chronic case no treatment seemed to avail at first, but later the application of an alcoholic solution of orthoform rendered the patient comfortable and diminished the severity and frequency of membrane formation.

DEATH UNDER CHLOROFORM.

AN inquest was held at Bristol on Jan. 7th to inquire into the circumstances attending the death of Florence Brain, aged three years, who died while undergoing an operation at the Bristol Royal Infirmary. It seems that the patient was admitted to the Bristol Royal Infirmary on Jan. 3rd, 1901, suffering from tuberculous peritonitis. On account of her varying condition operation was deferred several times until, on Jan. 5th, after a general consultation by the surgeons, it was decided to open the abdomen. The child had been vomiting for 14 hours and at the time of operation the temperature was 95° F. and the pulse-rate was 100, very small and weak. The heart was examined and found to be normal, and chloroform was given upon a piece of flannel stretched over a wire frame. The child took the anæsthetic fairly well and the operation was nearly completed, but while the stitches were being put in she began to come round, so a little more chloroform was given. After a breath or two respiration suddenly stopped. No more chloroform was given, the operation was stopped, and artificial respiration was performed for half a minute. Natural respiration re-commenced and a few more stitches were being put in when the breathing began to fail and was therefore supplemented by artificial respiration. The pulse up to the cessation of respiration had remained good. Artificial respiration was continued for some time; inversion of the body, application of hot fomentations over the heart, and administration of strychnine were all used but without effect. The colour of the patient remained throughout extremely good, no lividity of either lips or cheeks being noticed. The amount of chloroform used in all was about two drachms. A post-mortem examination showed very extensive tuberculous deposit throughout the abdomen, the intestines being matted together. There was, in addition, extensive tuberculous disease of the lungs and the mediastinal glands were caseous. The heart and brain were normal. Mr. H. F. Mole, house surgeon, said in evidence before the coroner that the child died partly from syncope and partly from severe tuberculous disease, and the jury returned a verdict in accordance with the medical evidence. The phenomena of the narcosis as described appear to have been of a normal kind until the point when upon returning consciousness a fresh administration of the anæsthetic was

attempted. We are, however, told that the child took the anæsthetic "fairly well," and possibly this implies that there was some difficulty earlier. It is matter of common experience that the resumption of consciousness in weakly children is marked by either faintness or a hurried and often crying respiration; in either case a fresh supply of chloroform will easily prove an overdose and paralyse the vasomotor system or respiration. In the present case the circulation does not appear to have flagged so that the child in its feeble condition probably inhaled too strong a vapour of chloroform when the mask was re-applied. We presume that no third attempt to give the chloroform was made—i.e., no more was inhaled after the first failure of respiration. Certain it seems that the exhausted state of the child was a potent factor in the fatality. We notice that no inhalation of ether was given as a restorative measure; it is certainly a matter of regret that so few anæsthetists employ ether by "the open method"—i.e., by dropping it on lint—in such cases as the one under comment. It is one which often answers extremely well and saves many accidents.

UNGUENTUM HYDRARGYRI B.P.

IT is well known that mercurial ointment is commonly sold at roughly a third of the strength of the formula laid down in the British Pharmacopœia. But of course when the B.P. preparation is asked for it should be supplied. That apparently was not the demand made recently by the person appointed to collect samples under the Food and Drugs Act at the instance of the Folkestone Town Council. He was supplied with the mild ointment which it is the custom of druggists to sell to ordinary purchasers. And so a deficiency of mercury was found in accordance with the standard adopted by the British Pharmacopœia. The town clerk was instructed to take the necessary legal proceedings, which, however, were ultimately withdrawn, the chairman of the sanitary committee expressing an opinion that where a thing was not sold in accordance with the standard of the British Pharmacopœia it ought to be so labeled; and there is a good deal to be said in favour of this view. Pharmacists, however, will hardly relish labeling their preparations as non-official, as though that description would be perfectly accurate in some cases, yet it is calculated to bring preparations so labeled under prejudice. The Bench granted two guineas as a sort of solatium to the defendant, whilst expressing no opinion on the aspects of the case.

THE MINISTRY AND THE LICENSING LAWS.

DURING the short session of Parliament held in December about 50 Unionist members met in Committee Room No. 17 and unanimously agreed on a memorial to the Prime Minister in favour of licensing reform being undertaken next session by the Government in accordance with the unanimous recommendations of the Royal Commission on the Licensing Laws. It was resolved to form a body to be called the Unionist Licensing Reform Committee, with Sir W. H. Houldsworth as chairman and Mr. E. Tritton as honorary secretary. The Primate has lately intimated that the bishops are unanimously in favour of legislation on certain lines, and are determined that in some form it shall be attempted. There can be no doubt that the leaders of the Nonconformist churches are equally anxious to see some legislation recognising and tending to reduce the enormous excess of drinking—the excess which the majority report of the Royal Commission in a euphemism calls "the superfluous drinking" of the country. There is a rumour that the Government contemplate the introduction of a measure on the subject. We sincerely trust that this rumour will prove to be well founded. If it is not so we venture to believe that they will offend some of their best supporters and many who, like ourselves, without party bias, are anxious about the health and social happiness of the people. We are on the eve of a series of Cabinet meetings. The war and foreign politics cannot entirely engross the whole attention of Parliament. Of all social questions that of the housing of the poor is the most urgent, as Lord Salisbury has recently told us. Social reformers maintain that good houses cannot be obtained for the poor without the help and coöperation of the poor themselves. Articles in our columns have recently shown that in many cases the dissolute habits of the poor immensely complicate the problem of housing them. But without some support from the State the poor will not resist the fascinations of the public-house which absorbs such a large and disproportionate share of their wages. We venture to hope that the Ministry will tackle this question and not leave its supporters speechless when taunted as a party with indifference on this subject. Almost every European nation is feeling that legislation must do more than it has done to arrest the degeneration, disease, and poverty traceable to "superfluous drinking." Our national pauperism undergoes no reduction corresponding to the improved means of the people, showing that the nation suffers from the diversion of capital spent over this vice.

ARSENICAL POISONING IN THE COUNTY OF SALOP.

WE have already pointed out that if the provisions of the Food and Drugs Act were carefully and systematically made use of the sale of beer contaminated with arsenic would soon be stopped. Pending, however, the conclusions of a Royal Commission we may hope that full advantage of existing legislative machinery will be taken. Amongst the first successful prosecutions have been those instituted in the county of Salop. At Newport in this county on Jan. 15th a prosecution supported by the county analyst and the county medical officer of health resulted in conviction and a fine of £5. The beer contained one-eighth of a grain of arsenious acid per gallon. It is desirable to point out that in future all analysts should report the exact amount of arsenic found to be present and not be content with simply saying that the poison was discovered. The borough authorities of Shrewsbury have also fined a man for a similar offence and other prosecutions are pending. It would appear that between 50 and 60 arsénical poisoning cases have occurred in the county, including 30 at least at Market Drayton, 15 at Whitchurch, two at Wellington, and one each at Oakengates, St. George's, and Shrewsbury. According to observations so far made the pigmentation and eruptions in these cases are not so marked as they were in the cases in the Manchester epidemic.

THE PREPARATION OF BLOOD FILMS.

THE examination of the blood as an aid to diagnosis is now practised much more frequently than formerly, and especially in cases of supposed malarial fever. One of the main difficulties is to obtain a satisfactory film. Many suggestions have been made and in the *Journal of Tropical Medicine* of Dec. 15th Mr. W. L. Braddon, F.R.C.S. Eng., Negri Sembilan, Malay Peninsula, publishes a method which he has found to give good results. The slides and coverslips are sterilised and thoroughly cleaned. If slides with coverslips attached are to be prepared, the slip is placed on the slide in such a position that one of its edges coincides exactly with that of the slide. For temporary use vaseline is smeared round the edges of the coverslip, except that which corresponds with the edge of the slide and a small portion of the opposite edge. For experimental purposes white cement should be employed instead of vaseline. For the preparation of paired coverslips two slips, preferably

square ones, are accurately superimposed and firmly pressed together, and the vaseline or cement is smeared over all the edges except one, which is left free as before, and a part of the opposite edge. On touching the drop of blood to be examined with the free edge of a slide or paired slip, the blood enters in a thin film in which the corpuscles are spread out with satisfactory uniformity, having suffered a minimum of change from exposure to air and none at all from handling or pressure. When the whole space has been slowly filled the edges and small openings previously untouched with vaseline or cement are closed by applying a little of the former with a small camel-hair brush. Mr. Braddon states that fresh blood so taken will keep longer than after any other process with which he is acquainted. He goes on to say that stains are best added by placing a drop on the surface from which the blood is drawn and puncturing through the drop. This process would seem to possess many advantages. The glasses and coverslips duly arranged, the specimens of blood can be obtained by persons unskilled in the technique required in other methods; and if it should be necessary to send the preparations some distance to be examined they can be packed for carriage with less fear of damage than if single coverslips are employed.

IDIOPATHIC INTERNAL HYDROCEPHALUS.

IN a recent contribution to the *Journal of Experimental Medicine* (Oct. 25th, 1900), by Dr. Charles W. Burr and Dr. D. J. McCarthy, attention is drawn to the fact that whereas internal hydrocephalus from mechanical causes is relatively common, idiopathic internal hydrocephalus is rare and has attracted the attention of clinical observers and pathologists only recently. The credit of having established idiopathic internal hydrocephalus as a distinct clinical and pathological entity belongs to Quincke who in 1896 described the two varieties, acute and chronic, of this affection. The acute variety is most frequent in children, in adults it usually follows cranial injury, acute or subacute alcoholic poisoning and infectious fevers, especially typhoid fever and pneumonia. The following case was that of a man, aged 33 years, who was admitted to the Philadelphia Hospital in April, 1899, with severe headache, great weakness, and abdominal pain. His family and personal histories were unimportant, except possibly that four years previously he had had typhoid fever. On the evening of his admission to hospital he was delirious, the head was retracted and the neck muscles were rigid, and the legs were strongly flexed upon the abdomen. The temperature was 102° F., the pulse was 82, and the respirations were 24 per minute. The head could not be flexed or moved laterally, all attempts at passive movement causing severe pain. There was no muscular rigidity elsewhere. The tongue was brown, the lips were cracked, and the abdomen was distended. The knee-jerks and plantar reflexes were absent. The urine contained a trace of albumin and a few hyaline casts and had a specific gravity of 1027. Widal's test was made repeatedly with the blood with negative results. The provisional diagnosis was acute meningitis. At the end of a week Kernig's sign was present. Herpes of the lips and nose and a bluish mottling of the skin now appeared. The mental state varied greatly, the patient being at one time restless, delirious, and incoherent, at another time stuporous, and at moments almost rational. The pupils were dilated and slight lateral nystagmus was present. The fundus oculi was normal on both sides. In a fortnight he improved a little, the pain disappeared, and he was mentally clear, "but he had no realisation of his being sick, and though too weak to stand maintained that he was very well. ..... He was trifling and jocose, and, as his sister said, altogether unlike his usual self." He now appeared like a man in the early stages of general paralysis of the insane. He improved physically and remained thus for a month when the temperature rose, the old symptoms returned, nystagmus became marked, subsultus tendinum was added, and he died. The necropsy was made the following day. On opening the skull the dura mater was tense and elastic. The cerebral convolutions were broadened and flattened so that the sulci were almost obliterated and appeared as lines beneath the pia. The cortex was pale and anæmic. The infundibulum was distended and on opening the ventricles a large amount of clear fluid escaped. The lateral ventricles and the aqueduct of Sylvius were distended and the ependyma was boggy and separated easily from the underlying tissue. The choroid plexuses were œdematous, swollen, and injected. The spinal cord was similarly affected. The heart and lungs were normal. Microscopical examination showed a large number of hyaloid bodies in the choroid plexuses and a marked ependymal proliferation in the lateral ventricles. The vessels beneath the ependyma were actively congested and were surrounded by round cells with nuclei slightly smaller than glia cells. The neuroglia cells also showed proliferative changes. The cortical and spinal nerve-cells stained by Nissl's and Weigert's methods showed nothing abnormal and the white matter of the cord showed no degeneration with Marchi's method. Auto-intoxication was believed to underlie this obscure affection in the present instance, as this would best explain the symptoms present.

"HOSPITAL MANNERS."

UNDER the above title a contemporary comments upon the discourtesy that is said to be met with from subordinate officials at hospitals. The criticism to which we are referring is based upon the alleged grievances of a would-be lady visitor. This lady's sense of the fitness of things was apparently first offended when she was asked to wait in a room adjoining the matron's room. When from the matron's room itself laughter was heard the would-be visitor's feelings were further outraged. Later she received, according to her account, a cool reception at the matron's hands, and her final "Good morning" met with no response. Now, all connected with hospitals know how much good and kindly work is done by lady visitors and would be deeply grieved to think that their efforts should ever receive any but the warmest welcome at the hands of the matron or any other hospital official. That there was any discourtesy on the part of the matron in the case referred to we are very loth to believe. The lady was admittedly a complete stranger to the hospital. Strangers in hospitals wander to the queerest places and have the queerest notions as to who and what are the persons and things they meet. To the average lady in a strange hospital every student is a physician or surgeon, and quite possibly any nurse, or even wardmaid, might be a matron. That a lady should have been impolitely spoken to by anyone is of course deplorable, but the discourtesy of which our contemporary complains is, we are perfectly certain, scarcely to be found in any London hospital.

ROYAL MEDICAL BENEVOLENT COLLEGE, EPSOM.

THE Earl of Rosebery, the President of the Royal Medical Benevolent College, has promised to take the chair at a festival dinner in aid of the fund for the pensioners and foundation scholars at the Hotel Cecil on Tuesday, April 16th. In consequence of heavy and unexpected charges which have arisen within the past few years for drainage and repairs money has had to be found, and the council are now in a state of serious financial embarrassment, although, as far as can be seen, the pressure is only of a temporary character. On Dec. 31st, 1900, a sum of £2500 was owing to the bankers. To liquidate this and to keep up the yearly aid to the aged pensioners and young foundation

scholars the aid of all interested in the welfare of the medical profession is earnestly solicited. Gentlemen willing to act as stewards or who desire to be present at the dinner will receive all information from the secretary, Mr. J. B. Lamb, at the office, 37, Soho-square, W.

LIEUTENANT INKSON, V.C., R.A.M.C.

FOR the second time within a year it is our proud duty to record the bestowal of the blue ribbon of service honours—the Victoria Cross—upon a member of the Royal Army Medical Corps. The last recipient was Major W. Babtie, C.M.G., V.C., R.A.M.C., and now the honour comes to Lieutenant E. T. Inkson, R.A.M.C., for the following act of courage. On Feb. 24th, 1900, Lieutenant Inkson carried Second Lieutenant Devenish (who was severely wounded and unable to walk) for three or four hundred yards under a very heavy fire to a place of safety. The ground over which Lieutenant Inkson had to move was much exposed, there being no cover available. In the name of the profession we congratulate Lieutenant Inkson upon the addition of his name to the national roll of heroes.

GARBAGE-MONGERS.

WE have on previous occasions expressed the opinion that a man who sells diseased meat for human consumption is no more nor less than a potential poisoner and should be treated as such. A peculiarly infamous case of the kind is reported from Aberdeen, where on Jan. 15th Mr. George Wood, a butcher and cattle-dealer, pleaded guilty to having sold to a firm of Government contractors a large quantity of unsound beef. The meat was going to be made into rations for the troops at the front. Wood was fined £50 and costs, with the alternative of 60 days' imprisonment. Why any alternative was offered we fail to see, for no more dastardly crime could be imagined than that of attempting to poison Her Majesty's troops on active service.

THE RÖNTGEN SOCIETY.

THE council of this society announce that the President, Dr. J. Macintyre of Glasgow, has placed at their disposal a gold medal to be awarded to the maker of the best practical x-ray tube for both photographic and screen work. The competition is open to makers in any country. The jury will be chosen by the President and council of the society, and their names will be announced in the *Times* of March 1st Tubes intended for competition must be sent in addressed to the Röntgen Society, 20, Hanover-square, London, W., marked "Tube for Competition," the package containing the full name and address of the sender, and must reach the society not later than May 1st, 1901. The conditions of the competition can be obtained on application to Dr. F. Harrison Low, honorary secretary, 12, Sinclair-gardens, West Kensington, London, W.

THE ELECTION OF A DIRECT REPRESENTATIVE FOR IRELAND ON THE GENERAL MEDICAL COUNCIL.

ON Feb. 28th, 1901, the term for which Sir William Thomson was elected as Direct Representative of the registered practitioners in Ireland will expire. For some time past the General Medical Council has been taking steps in accordance with the Medical Acts preliminary to the issue of voting papers for the election. The issue of such papers will take place between Jan. 21st and 24th. The last day for their return will be Jan. 31st. The counting of votes will take place between Feb. 1st and Feb. 4th. The meeting of the Branch Council for Ireland to certify the result of the election will be on Feb. 5th, and the declaration of the poll by the returning officer will take place on Feb. 6th. The general impression is that Sir William Thomson will be re-elected, though we learnt with some surprise a few days ago that a contest is possible. It will be a pity to bring any second candidate into the field unless there is a good chance of his success. Some feeling has been expressed in favour of the nomination of a Poor-law medical officer by the council of the Irish Medical Association. But a man is wanted who will represent the whole profession in Ireland, including its Poor-law medical officers. And no man is more capable of doing this with dignity and effect than Sir William Thomson, who is deservedly regarded as one of the most useful, independent, and well-informed members of the Council.

THE REGULATION OF THE SALE OF CARBOLIC ACID.

A CIRCULAR letter has been sent to the sanitary authorities throughout the country admonishing them as to the precautions to be taken in dealing with carbolic acid. As we announced in THE LANCET of Sept 8th, 1900 (p. 752), an Order was made by the Privy Council in July, 1900, approving a resolution passed by the Pharmaceutical Society of Great Britain that liquid preparations of carbolic acid and its homologues containing more than 3 per cent. of those substances should, except in certain cases connected with agriculture and horticulture, be deemed poisons within the meaning of the Pharmacy Act, 1868. It is now pointed out by the Local Government Board that whenever the disinfectant employed is carbolic acid or any other poison within the meaning of the Pharmacy Act, 1868, only bottles similar to those prescribed by the regulations adopted by the Pharmaceutical Society of Great Britain and approved by the Privy Council on Jan. 31st, 1899, should be used to contain it. The regulations in regard to the keeping, dispensing, and selling of poisons are now as follows:—1. That in the keeping of poisons each bottle, vessel, box, or package containing a poison be labeled with the name of the article and also with some distinctive mark indicating that it contains poison. 2. Also that in the keeping of poisons each poison be kept on one or other of the following systems—viz., (*a*) in a bottle or vessel tied over, capped, locked, or otherwise secured in a manner different from that in which bottles or vessels containing ordinary articles are secured in the same warehouse, shop, or dispensary; or (*b*) in a bottle or vessel rendered distinguishable by touch from the bottles or vessels in which ordinary articles are kept in the same warehouse, shop, or dispensary; or (*c*) in a bottle, vessel, box, or package kept in a room or cupboard set apart for dangerous articles. 3. That in the dispensing and selling of poisons, all liniments, embrocations, and lotions containing poison be sent out in bottles rendered distinguishable by touch from ordinary medicine bottles, and that there be affixed to each such bottle (in addition to the name of the article and to any particular instructions for its use) a label giving notice that the contents of the bottle are not to be taken internally. We may observe that the word "homologues" is retained, although, as we have pointed out, there is some doubt as to its exact meaning in this case, and, moreover, there are homologues of phenol which are non-poisonous. We believe that since this Order came into operation last September the number of cases of self-poisoning by means of carbolic acid has sensibly diminished. The total number of cases of self-poisoning by all agencies is, however, maintained, hydrochloric acid or common spirits of salts appearing to have supplanted carbolic acid as the most usual. We should not be surprised if this mineral acid has next to be placed under the same restrictions as carbolic acid as to its sale and keeping.

PROFESSOR SKLIFOSSOVSKY presided on Friday last, Jan. 11th, over a Surgical Congress at Moscow, at which many prominent Russian medical men were present.

PROFESSOR SKLIFOSSOVSKY.

A ROYAL Commission has been appointed to make investigations respecting the beer-poisoning epidemic. The Commissioners are Lord Kelvin, Sir W. Hart Dyke, Sir W. S. Church (President of the Royal College of Physicians of London), Professor T. E. Thorpe (Government Analyst), Mr. H. Cosmo Bonsor, and Dr. B. A. Whitelegge (H.M. Chief Inspector of Factories). Dr. G. S. Buchanan, one of the medical inspectors of the Local Government Board, is the secretary to the Commission. The instructions to the Commissioners are to ascertain with respect to England and Wales: 1. The amount of recent exceptional sickness and death attributable to poisoning by arsenic. 2. Whether such exceptional sickness and death have been due to arsenic in beer or in other articles of food or drink, and, if so, (*a*) to what extent; (*b*) by what ingredients or in what manner the arsenic was conveyed; and (*c*) in what way any such ingredients became arsenicated. 3. If it is found that exceptional sickness and death have been due to arsenic in beer or in other articles of food or drink, by what safeguards the introduction of arsenic therein can be prevented.

AN interesting series of articles from the pen of Mr. Bertram Wilson has appeared in *Young Oxford*, a magazine "of constructive thought and devoted to the Ruskin Hall movement." The articles are freely illustrated, chiefly with types of the victims of lead-poisoning. Mr. Bertram Wilson enters a forcible argument in favour of the abolition of raw lead in pottery making. Reference is made to those firms now producing leadless-glazed ware, specimens of which experts pronounce to be equal in beauty and finish to the old lead-glazed ware. A selection of these may be seen at Messrs. Mortlock's, Limited, 466, Oxford-street, and at Jermyn street Museum.

SIR CHRISTOPHER NIXON, President of the Royal College of Physicians of Ireland, will entertain His Excellency the Lord Lieutenant and the Chief Secretary for Ireland, with the Fellows of the College and many distinguished guests, at a banquet on Jan. 26th, to be held in the College hall.

AT an inquest at Manchester on Wednesday last some evidence was given which may throw a strong light on the beer poisoning epidemic. It was admitted by a witness, the representative of a firm of vitriol makers, that owing to pressure of orders for pure or "brimstone acid" his firm had discontinued the supply of sulphur-derived, or arsenic-free acid to a firm of glucose makers and sent in its place "stone" acid containing the common impurities arising from the burning of pyrites. The witness could not remember whether the change was notified to the clients of his firm.

IN recognition of services rendered in connexion with the recent military operations in Ashanti the Queen has appointed Mr. Donald Keith McDowell, principal medical officer of the West African Frontier Force on the Niger, lately serving as principal medical officer of the Ashanti Field Force, to be a Companion of the Most Distinguished Order of St. Michael and St. George.

THE annual dinner of the West London Medico-Chirurgical Society will be held at Frascati's Restaurant, Oxford-street, on Wednesday evening, Feb. 13th, at 7 for 7.30 P.M. Communications should be made to Dr. G. P. Shuter, Oaklands, Chiswick-lane, W.

THE Lord President of the Council, in the exercise of his powers under the Charter of the University of Wales, has appointed Dr. Isambard Owen to be a life member of the University Court, in succession to the late Marquis of Bute.

THE new medical training home of the Church Missionary Society in Tanner-street, Borough, will be opened on Jan. 21st, at 3 P.M., by the Countess of Chichester.

SIR JAMES SAWYER has been elected a Fellow of the Society of Antiquaries.

REFLECTIONS ON THERAPEUTICS.

BY HARRY CAMPBELL, M.D., B.S., F.R.C.P. LOND.,
PHYSICIAN TO THE NORTH-WEST LONDON HOSPITAL AND TO THE WEST END HOSPITAL FOR DISEASES OF THE NERVOUS SYSTEM.

III.[1]

HABIT VIEWED FROM THE THERAPEUTIC STANDPOINT.

Periodic habits.—Bodily processes, especially those occurring in the nervous system, tend by repetition to recur more and more easily, and when by frequent repetition considerable facility has been attained we say a habit has been formed. Habits as popularly understood consist for the most part of acts which, voluntarily or semi-voluntarily initiated, tend by constant iteration to recur with little or no volition. Such are nail-biting, sniffing, blinking, jerking of the head and kindred movements (habit spasms), eating fast, or getting up early or late. Habits may also be formed quite independently of mental processes. If, for instance, a cardiac intermission is started from any cause the heart may, by mere repetition of the process, get into the habit of intermitting, and continue to intermit, after the original cause has been removed; in like manner the whoop of whooping-cough may persist for some time after complete recovery from the disease; similarly, the bladder may acquire the habit of spontaneously emptying itself during sleep; or again, the repeated iteration of a neuralgic seizure may lead to a spontaneous occurrence of the attacks after the removal of the exciting cause.

Now, inasmuch as some habits are injurious to health, or objectionable for other reasons, while others are favourable to health, the physician has to reckon with them as factors in therapeutics. Manifestly he will seek to break his patients of injurious habits and to inculcate such as are beneficial, and in this way the force of habit may be directed to therapeutic ends with the best results. But while habits which tend to promote health cannot be too assiduously cultivated, one must be on one's guard against

[1] No. II. was published in THE LANCET of Jan. 12th, 1901, p. 122.

becoming the slave of any habit. With increasing years habits grow on us, the protoplasm losing its plasticity and becoming more "set," as it were. This is a senile change, and we should all seek to ward off the disabilities of age and to retain our plasticity as long as possible. But even before the advent of senility, a person may, if he is not watchful over himself, get to be such a creature of habit, so bound down by routine, as to be little more than a machine; for it is to be noted that the more stereotyped a man's actions, the more limited is his sphere of activity and the less volitional is he—the more closely, in short, does he approximate to the instinct-led, machine-like brutes.[2] Moreover, there are grave inconveniences attaching to deeply-rooted, imperious habits. If an individual is only able to eat particular kinds of food, at particular times, and cooked in a particular way, he may be upset, "thrown out of gear," as he would say, when he finds himself so placed that he cannot secure all these three conditions to his liking. Sir James Paget, who, in his "Studies from Old Case Books," strongly insists upon the inadvisability of becoming the victims of habit, goes so far as to assert that a person should not get into the habit of sleeping always on one side or of going to stool at a regular hour. No doubt there is much soundness in this advice, which, generalised, amounts to this: keep as plastic and adaptable as you can; do not allow yourself to be over-mastered by habit. At the same time, his position is probably somewhat extreme, only a few fortunate individuals being capable of following out his advice as fully as he was himself able. Doubtless, however, it should be carried out as far as is consistent with health; and if only for the moral effect of the self-denial and as an exercise in self-control, it is a good plan to abandon for a time habits such as smoking, tea-drinking, and the like. "I believe," says Ruskin in a passage which I came across the other day, in which he alludes to the asceticism of the early Christian centuries, "no reasonable person will wish, and no honest person dare to deny, the benefits he has occasionally felt *both in mind and body* [the italics are mine] during periods of accidental privation from luxury and exposure to danger."[3]

Habituation to circumstances.—So far I have been considering only the habits which pertain essentially to the nervous system and are periodic in nature. But "habit" is wider in its scope than these. The animal organism possesses the property of becoming adaptively modified, or "habituated," as we say, to circumstances, and this property also has to be reckoned with in treatment. By virtue of it structure and function may be profoundly modified,[4] so as to enable the organism to work in harmony with the influences brought to bear upon it. In this way it is that man becomes adaptively modified by the conditions of his life—by food, climate, occupation, and so forth. These conditions may be such as to cause actual disease when first encountered, but by virtue of his adaptability he becomes gradually moulded by them, reacting to them ever more and more harmoniously, until at length perfect harmony may be attained, when we say that he is perfectly adapted, or habituated, to his environment. On the other hand, the environment may be of a kind to which the organism, human or other, can never completely adapt itself; but even so, it always strives to, and with varying degrees of success—from almost complete failure to perfect success. When perfect adaptation cannot by any possibility be attained we must regard the environment as necessarily morbid. Note this, however, that some adaptation tends to occur even to unmistakeably morbid conditions,[5] their morbidity lessening; and, further, that even when the morbidity seems to have entirely disappeared, some hidden morbid action may still be going on. Of this I shall presently give examples.

Instances of complete adaptation.—Acclimatisation, or habituation to a particular climate, may be complete—i.e., a climate which at first causes ill-health may gradually cease to do so. It is popularly held that a person's native air is the one best suited to him, and if it be so we may explain the fact by reference to early acclimatisation. It is a matter of common observation that people get accustomed to different kinds of food. Every nation has its own national diet, and when a person of one nationality takes to the food of another, he is at first apt to be upset by it, afterwards, however, experiencing no discomfort. It has recently been found that the composition of the digestive juices is greatly influenced by the kind of diet taken, each diet exciting just that particular kind of secretion which is best adapted to its digestion. In this way the glands acquire habits of secretion, so that when a long-accustomed diet is changed it may be some time before the glands can learn to pour out the appropriate secretion. Those who are in the habit of eating bulky food containing an abundance of fibrous, indigestible material get acute indigestion if fed on refined foods, the alimentary tract no longer being adequately stimulated by food sufficiently coarse and bulky. The contrary is equally true. Again, a person accustomed to an active out-door life is sure to suffer in health if he suddenly changes this mode of life for a sedentary one; and, on the other hand, one who leads a sedentary life may become so adapted to it that a very active life would do him more harm than good.

Partial adaptation to a morbid environment.—Let us now consider those cases where partial adaptation to a necessarily morbid environment takes place. Tobacco-smoking affords a good instance. An amount of smoking which in the beginner causes alarming collapse can be borne by the *habitué* without apparent harm—perhaps without any harm at all; but the fact that such serious effects are produced in the beginner by very small quantities of tobacco suggests that tobacco-smoking in any but the smallest quantities is necessarily poisonous, and that though the poisonous action is diminished by habituation, it never quite disappears; and experience seems to show that tobacco in larger quantities is always injurious, though the evil effects may be unperceived. The same is probably true of alcohol. Some contend that even small quantities act injuriously—certainly large amounts do; nevertheless the individual can to some extent adapt himself to pernicious doses. An amount which in the beginner produces mental obfuscation, i.e., a decidedly morbid effect, in the *habitué* produces no such result—a circumstance which may be taken to indicate that the agent is no longer morbid to him, or, though still morbid, that it is so in a less degree; but whatever may be thought of the effect of small quantities, it is quite certain that alcohol in large amounts does actually produce evil effects, though these may not be recognised. In a like manner a person may habituate himself to eat with comparatively little inconvenience an amount of food which, without such gradual habituation, it would be impossible for him to eat, the morbid effects, though still persisting, becoming less and less obtrusive. Let me repeat, then, that habituation may conceal the evil effects of a nocuous agent and that we must not too hastily assume that because no evil effect is perceived therefore none is taking place.

The fact that partial adaptation to a morbid agent may occur suggests a further thought. It may so happen that an individual has become so far adapted to a nocuous agent, his entire system so grown to and modified by it, that more evil may accrue from suddenly removing him from its influence than from allowing him to remain under it. Thus an elderly man with a feeble heart, accustomed for many years to generous living, may be made worse by sudden deprivation of the morbid agents—by depriving him of all alcohol and putting him upon a bland diet. We must beware, in short, of the harm which may result from suddenly altering the patient's conditions of life even though those conditions are in themselves injurious, and the older the patient the more should we be bound by this principle. Indeed, for that matter, we should beware of sudden changes of any sort—e.g., from mixed feeding to pure vegetarianism, or from a fattening diet to severe Banting treatment, and the more we keep in view the law of habituation the less likely are we to err in this respect. Nevertheless, in the case of an unmistakeably nocuous agent it is generally advisable to remove the patient from its influence with all possible speed. Even in the case of chronic alcoholism experience shows that the most effective treatment consists in promptly and peremptorily cutting off all alcohol. Again, if a person has been eating too much, we may with safety at once limit the food to a sufficiency, though it may be more politic to reduce the amount gradually.

---

[3] The Bible of Amiens, iii., The Lion Tamer.

[4] It is needful to distinguish between *adaptation* and *adaptability*. The latter is the power of becoming adapted. It is one of the most remarkable attributes of living organisms, one, as I have shown elsewhere, that has slowly and laboriously evolved. See "The Differences in the Nervous Organisation of Men and Women."

[5] See Campbell: "The Physiological Aspects of Disease," St. Bartholomew's Hospital Reports, 1895.

I will conclude my remarks on habit by quoting some observations of Sir Samuel Wilks. That physician is reported to have said to an interviewer: "Habit is a great deal; it is second nature. A man accustomed to walk 12 miles a day cannot do without it. Every one has a natural temperament. Follow that and avoid excesses. That's all. A quack may tell you you must eat an ounce of albumen, so much starch, so much water, and so on, and what should you do? Go and have a nice chop. The instincts of the people are right. And what about exercise? Jenner would have said to you, 'I never walk at all, except from my house into my carriage. I hate walking and if I could I would get my servants to carry me to bed.' That was Sir William Jenner, the Queen's eminent physician. In the last three or four centuries we have done better intellectual work than ever before, and these have been the times of tea, coffee, tobacco, and alcohol. What can you make of that? Again I say, follow your instincts."[6]

No doubt there is much wisdom in these words, but they must not be interpreted too literally; they must merely be taken as a protest against a too fussy interference with a man's habits and instincts. Nothing is more certain than that inclination often leads a man astray.

THE WAR IN SOUTH AFRICA.

NOTWITHSTANDING that the Boers are displaying great activity at the present time, that their forces, split up into numerous *quasi*-independent bodies, are carrying on their operations in numerous directions extending over a wide geographical area and that they are boldly making raiding incursions in the direction of Cape Town, the news is not, on the whole, unfavourable. If, on the one hand, the anticipations of military optimists have not been realised, on the other hand, it must be borne in mind that what many people regard as unsatisfactory or of serious import in the present position is, after all, of a temporary nature, that the political danger which was feared—viz., that the Dutch population of Cape Colony would rise in favour of the Boers—has not been realised, and that of the many recent attacks upon our lines of communication none have really been successful. It is the vast extent of the country over which the operations have to be extended that makes them so difficult and embarrassing. The systematic pursuit of a definite plan of action, the disposition of the British forces, and even the character of the fighting have now to be adapted to the altered conditions brought about by roving bands of raiders and filibusters. A very large addition to our mounted forces in South Africa is no doubt necessary and will be made. Still, the actual news from South Africa does not seem to justify the pessimistic tone in which some people indulge. Raiding on an extensive scale on the part of the Boers will be a source of much trouble to Lord Kitchener and may prolong the war, but this system of warfare was to be expected on their part and it cannot undo what has been already accomplished or affect the final issue. Be all this as it may, however, the prolongation of the war necessarily carries with it increased sickness and loss of life from wounds and disease, and especially from the latter. The lists of those returned as dangerously ill are long and, for the most part, made up of cases of enteric fever

According to the latest reports from Lieutenant-Colonel Sloggett, R.A.M.C., commandant of the Yeomanry hospital, there were 25 officers and 505 non-commissioned officers and men at Deelfontein on Dec 24th last, including Lieutenant de Wet (nephew of General de Wet), who was suffering from a severe gunshot wound of the knee. Colonel Sloggett reports that he regrets to say that enteric fever is increasing and that there are several serious cases under treatment in the hospital.

Surgeon-Major Kilkelly of the Grenadier Guards, commandant of the hospital at Pretoria, reported on Dec. 20th that there remained under treatment 40 officers and 389 non-commissioned officers and men. Enteric fever was still prevalent in the vicinity. Of the 223 recent admissions 93 were members of General Clements's force from Reitfontein. Surgeon-Major Kilkelly mentioned that since the hospital was opened on August 18th, 201 officers and 1713 non-commissioned officers and men had been treated by this section of the Imperial Yeomanry hospitals, making a total of 1914 patients. Captain Turner, principal medical officer of the Imperial Yeomanry Branch Hospital at M'Kenzie's Farm, Maitland, stated that on Dec. 21st there remained in that hospital 51 patients, of whom 43 were yeomen, two being officers. He had just been enabled to erect two new huts for additional patients.

[6] Sir Samuel Wilks informs me that though the above is by no means a strictly accurate account of what he actually did say (and that altogether informally) he agrees with the general drift of the remarks

THE MEDICAL PROFESSION AND THE WORKING MAN.[1]

THE following has been addressed by "A Birmingham Consultant" to the working-men of Birmingham. It is an open letter dealing with their relations to the medical profession and having special reference to the recent experiment of the so-called "Consultative Institute." We reproduce it in our columns because we consider it to be an excellent exposition of the mutual position that the practitioner, whether consultant or general, should occupy towards that enormous and enormously important section of his *clientèle*—the working-man.

DEAR SIRS,—As a member of the profession which has incontestably proved itself for some centuries now to be your friend, and, indeed, the friend of all classes of suffering humanity, irrespective of purse or of anything but genuine need (we are not friends to humbug), I claim a generous and sympathetic hearing from you as I try to explain some of the points now at issue between the medical profession, yourselves, and some of the leaders of the Hospital Saturday movement. In doing this I would ask you to remember that we, who consistently give a great portion of our lives to your service and who, if we finally get well-to-do, obtain this competence chiefly out of the pockets of the rich and not out of the pockets of the poor, are at least quite as deserving of consideration and respect as those employers of labour (estimable men though they be) who begin to make big fortunes from their youth up and this directly by the employment of your labour.

1. From your letters you are evidently dissatisfied with the general practitioner, or, as you rather rudely term him, the "G.P." Will you allow me to tell you that you are largely responsible for this? When provident societies and clubs were first started he was perhaps too generously glad to help you, and between you both you have compounded a system for which you are supposed to obtain good medical attendance and medicine at one penny a week or even less than this. Of course you do not obtain it. You cannot obtain it except in isolated instances. The penny fee does not amount to a living wage for the poor practitioner you employ, and the utmost you can expect from him as he tries to see his 70 or 80 patients in the day is a kind word and a bottle of something which shall not injure you. He himself, if I understand him aright, will not take grave exception to my description of your relations, and ready and anxious though he be for opportunities of better work, will acknowledge that he cannot give this, and that you and circumstance are making his work shoddy and his life a burden.

2. Having succeeded in manufacturing a cheap and shoddy method of attendance at your homes you are now dissatisfied. You find, perhaps, that diseases are neglected and complaints overlooked. What is the remedy? Your wise and clever counsellors proceed to try and make for you a cheap and shoddy consultant, or what they call a consultant. In the present instance they choose a young man who has passed the examinations in Dublin successfully but who has never held any hospital appointment, and, so far as we know, has not done any original work. He comes to the City without any facilities for higher and scientific work, and is necessarily cut off by his own action from all the best avenues of professional education and enterprise. The authoritative declaration by the General Medical Council that his position is unprofessional now absolutely marks and, for the present, fixes this isolation. He is labelled a consultant by the wiseacres who exploit him, but of course he is not one. Even if he was just the stuff from which in course of time a true consultant might be developed the very terms of his employment would militate against this development. He is not his own master. As the hired servant of his committee every day is portioned out for him by them for the convenience of the public, and if, as his masters hope, the work become more than self-supporting, a dreary round of toil ensues which is fatal to all progress. Crushed between the upper and the nether millstones of his committee and his public he cannot well be anything but passive to the grinding, until every trace of originality and independence is finally destroyed in him.

3. How, then, is a true consultant made? The leaders in their profession are always those who have voluntarily made the task of money-getting subservient to the study of disease. Only a portion of this study is involved in the actual seeing of patients, the study which is of quite as great or greater importance to the consultant's progress is that which he undertakes, without any immediate fee or reward, in the post-mortem room, in the laboratory, in the operating theatre, in the museum, at the meetings of learned societies, and in his own study. For this strenuous life, devoted to the mastering of his profession, a delicate and careful apportioning of time is needed, a division of his day proportionate both to the strength and needs of the master. The consultant must emphatically be his own master. When he sees before

[1] Published by Cornish Brothers, 37, New-street, Birmingham, 1900. 1*d*.

him a new problem needing elucidation or some promising opening for special work he should be free at once to narrow down his energies to the special object needing them. If his chamber practice be too exacting he must be at liberty by raising his fees to lessen his work in this direction. If he require to visit other cities either at home or abroad he and his patients must be content to accept a temporary loss until the work is carried through. Whatever engagements he undertakes he will undoubtedly keep, but these should be voluntary and consistent with that utter devotion to his profession which should be the mainspring of his life.

I am drawing no ideal picture. What I have been describing is, indeed, the actual life of some of the best consultants personally known to me in Birmingham—consultants who, though charging good fees from those who are able to pay them, are not making large incomes but spending much, if not most, of their time in original work and teaching, increasing their own knowledge and that of the profession generally in the special field of medicine or surgery which is their present study, and so acquiring a solid reputation among their brethren.

4. Are such consultants inapproachable by any but wealthy patients? By no means. The very poorest can see them at the hospitals, and those less badly off but unable to pay the usual fee can always, directly or indirectly, ask for special consideration. This when really deserved is, in my experience, always granted. But a man of this stamp (and anyone lower than this in aim and work can only be a bogus consultant) will not be dictated to. He will not be made to see Mr. Jones or Mr. Smith against his will, or be made to see 30 patients and receive 30 half-guinea fees during the course of the day to the exclusion of all other work and impairment of his ideal. However much you may seek after it and try for it you will never make such a man see an indefinite number of you at half-a-guinea a time without "by your leave" or explanation. Understand this, realise it well, and you will never again make the mistake of supposing that you can hire a real consultant and exploit him at your will.

5. But you may ask me, "What then should we do to improve our relations with the medical profession and to obtain better advice and attendance not only for ourselves but for all self-respecting families with little incomes?" Let me tell you. First, as regards those of you who are provident and belong to medical clubs and sick societies. We shall want that half-a-guinea you think of throwing away at the so-called Consultative Institute—which is, after all, only the office or room of a very expensive general practitioner—and by help of it you may do a very great deal. Band yourselves together to alter your club rules, or if you cannot do this, start fresh clubs for medical attendance and let half-a-guinea a year be your regular insurance premium to your doctor. For this you may expect and obtain that care and consideration which your illness may demand. If only your financial relations with him are reasonable and right so that he can afford to give you time and trouble you will find that the general practitioner is much more worthy of your warm appreciation and a much more able guide than at present you have any conception of. Never in the whole history of the profession was the education for it made so stringent, so protracted, and so costly. No other profession is really so expensive and so onerous in its demands, and the qualified practitioner who has successfully passed his examinations is usually far above the average man both in general intelligence and in special knowledge. He may not and will not know everything—you must not expect this—but if you do not degrade him as your slave you may look up to him as your friend. When you want the services of a consultant or specialist, and are unable to pay the usual fees, speak to this friend who knows your circumstances, and he will speak for you to the consultant.

But one difficulty lies in the path of the general practitioner and yourselves when arranging for a consultation—a difficulty that has never been fairly met by those who insure against ordinary medical attendance. The consultation is a very disturbing element in general practice. It upsets the order of the day, and by interference with the general course of work costs the practitioner a very considerable amount of extra trouble. If the practitioner then is to welcome the consultation, he must be adequately recompensed for the accompanying trouble. How is this to be done? I think a portion of the half-guinea (perhaps the sixpence will be sufficient) should be set aside for this purpose, and from the small fund accruing a fee of four or five shillings should be available to be paid directly to the practitioner for every consultation. In this way the requirements of the practitioner might possibly be met without any further call on the resources of the patient other than that necessitated by the consultant's fee.

Secondly, as regards those who do not insure against illness, but are only able to pay very moderate fees for attendance. One of your great difficulties—perhaps your chief difficulty—is the danger of a doctor's bill for prolonged attendance and medicine, and you would rather when you consult a doctor pay a somewhat larger fee and have your prescription or advice, than be given a bottle of medicine and told to attend indefinitely. Well, then, say so when you consult your doctor, and I have no doubt he will oblige you. There are some general practitioners who specially cultivate this kind of practice. In the treatment of diseases of special organs there are also specialists who may be consulted at a fee of one guinea or half a guinea, but every practitioner, without exception, will receive a request for such attendance with every consideration and respect, and unless he sees grave reason against it (as in acute disease requiring careful watching) will willingly accede to the patient's desire. Even in these cases of acute and severe illness among those who are poorly off, the practitioner is usually willing to receive some system of weekly payment, so as to avoid the necessity of a long and heavy account.

6. I have dealt rather extensively with the difficulties of the patient and general practitioner, because these lie at the root of all the other difficulties between the patient and consultant. Set these initial difficulties right and no genuine sufferer need go unrelieved if relief be anywhere attainable. The natural channel of communication between the patient and the consultant is the medical attendant or general practitioner, and no other is so right or fitting. Therefore, see to it that this channel is pure and effective. See to it that your doctor is not the overtasked slave of a medical aid association, but your independent adviser, who is properly and justly paid a reasonable fee for his services.

And when you need a consultant, if your doctor refuses to advise you, inquire for the physician, or surgeon, or specialist whose hospital work in your city is both well known and honourable, and do not be misled by the lax morality of the open market which booms the shoddy garment and the quack medicine, and now is even attempting to invade professional life with unhallowed advertisement.

Birmingham, Dec. 15th, 1900.

Birmingham is a shrewd city and an important centre of thought. The Birmingham working-man ought to be brought to see that it is to his direct advantage to pay those whom Mr. Arthur Chamberlain calls "street doctors" properly. For in this way he will have a ready help in need as well as a medium through whom he can obtain the services of genuine consultant medical men upon such terms as his means warrant.

SCOTTISH POOR-LAW MEDICAL OFFICERS' ASSOCIATION.

THE following is the annual report of this association which has just been presented by the officers:—

During the past year the committee met nine times, the average attendance being eight members.

The Bill to amend the Local Government (Scotland) Act was read a first time on April 3rd. Several attempts to get a second reading were made but, unfortunately, without success. Alexander Cross, Esq., M.P., will again introduce the Bill on the assembling of Parliament. Would each individual member of the Poor-law medical service approach his Member of Parliament, personally or by letter, asking him to give our Bill his support and, if possible, assist Mr. Cross in the ballot? Petitions in favour of our Bill were presented to Parliament by the Aberdeen, Border Counties, Dundee, Edinburgh, Glasgow, Perth, and Stirling branches of the British Medical Association, also by the Glasgow Medico-Chirurgical, Glasgow Southern, and Glasgow Eastern Medical Societies.

A voluminous correspondence has been carried on during the past year with several parochial medical officers in the highlands and islands emphasising their special grievances (official residences, payment of locum tenens, &c.). Your committee after careful consideration could only come to the conclusion that while those special grievances were *real and clamant*, it was impossible to bring them before parish councils with any hope of success so long as medical officers were liable to dismissal without any cause being assigned, but that those grievances would require to wait until a more secure tenure of office was secured. Your committee regret that this finding has *not* given universal satisfaction to our friends in the highlands and islands.

In response to inquiries from a number of members in various parts of the country, the question of fees for lunacy and vaccination defaulters was brought prominently before the committee. From inquiries made it appears the utmost variety exists in regard to payment of fees under the Lunacy and Vaccination Acts. Each parish council appears to be a law unto itself, notwithstanding the regulations of the Local Government Board, which are very precise and distinct. Thus, in the rules issued in 1897, on page 108, it is distinctly stated that the fees under the Lunacy Act are *not* to be included in the salary of the medical officer under the Poor-law Act. And also on page 175 it is distinctly stated that the remuneration for vaccination shall be by fees for every child the medical officer may have visited for the purpose of vaccination. Now, what do we find?

LUNACY.

1. We believe some parish councils, acting on the instruction for their guidance, pay a fee of 21*s.* for every certificate of lunacy.
2. Some parish councils *pay no fee* for lunacy certificates belonging to their own parish, but pay a fee of 21*s.* for each lunacy certificate belonging to another parish.
3. Some parish councils *pay no fee* for lunacy certificates belonging to their own parish and *no fee* for lunacy certificates belonging to other parishes, but in making up their accounts against other parishes *always charge a fee of 21s.* for each lunacy certificate.

VACCINATION.

1. We believe some parish councils pay no fees for vaccination and may or may not grant their medical officer a lump sum.
2. Some parish councils pay only for those cases successfully vaccinated by the medical officer instead of paying for every case in the list furnished by the inspector whether the case has been previously vaccinated, unfit for vaccination, not found, or dead.
2. Some parish councils, acting up to the regulations, pay for every case on the list furnished by the inspector.

Your committee think that the attention of the Local Government Board ought to be called to those flagrant deviations from their official rules for the guidance of parish councils.

Dr. GILBERT CAMPBELL, 14, Hamilton Crescent, Partick, Chairman.
Dr. MATTHEW MARTIN, 737, Gallowgate, Glasgow, Treasurer.
Dr. W. L. MUIR, 1, Seton Terrace, Glasgow, Secretary.

Glasgow, January, 1901.

BRISTOL DISPENSARY.— The annual report of the Bristol Dispensary for 1900, which has just been issued, states that 10,060 patients were treated during the year and that medical assistance was also given in 24 difficult midwifery cases. The committee add that the branch of the dispensary at Bedminster is much appreciated and that the number of patients attended is larger than in the preceding year. The financial statement shows that the number of subscriptions has declined during the past year.

HISTORY OF THE HOUSING QUESTION IN LONDON.

PART II.[1]

UNDER THE COUNTY COUNCIL.

IT was not, as we have seen, till 1889 that London at last possessed a municipality. It is true that instead of being called the Municipal Council of London it is denominated the County Council, and that instead of having its headquarters in the City the very heart of the metropolis has been subtracted from the metropolitan jurisdiction and still continues to govern itself as if it were a separate town. This is one of those many anomalies in which the British nation seems to take special delight and helps to confirm the opinion, widely entertained on the continent, that all Englishmen are more or less eccentric. This is not, however, the time or place to discuss whether the City should have been included as one of the constituencies of the London County Council. It is more to the present purpose to note that the County Council had no sooner been elected than it began to study what amendments were required to render the Acts on the housing question more effective, and it was able to make representations on the subject by the end of the first year. This was promptly followed by legislation, and we had the Housing of the Working Classes Act of 1890, so it cannot be said that much time was lost, at least at this stage of the proceeding. It would take much space to explain all the bearings of this Act. Divided into seven parts, the first three parts apply especially to London and the remainder to the provinces and to Scotland. Part I. constituted the County Council as the only authority for carrying out Cross's Acts of 1875, 1879, and 1882, which were consolidated and amended and which deal with large areas. Of great practical importance was the creation of the post of medical officer of health to the County Council, thus bringing into existence a superior and supervising sanitary authority who is independent of the local vestries or district boards, now replaced by the new borough councils. Thus, if the smaller local authorities fail to act the medical officer of the County Council can intervene, and the County Council can carry out a scheme where the local body fails. Then it is stipulated in Part I. of the Act of 1890 that the compensation paid to the expropriated proprietors of condemned houses shall "be based on the rental which would have been obtainable if the house or premises were occupied for legal purposes and only by the number of persons whom the house or premises were, under all the circumstances of the case, fitted to accommodate without such overcrowding as is dangerous or injurious to the health of the inmates." Further, if the house was in such a condition as to create a nuisance the likely cost of doing away with such nuisance and putting the house in proper repair is to be deducted from the estimated value of the premises. Finally, if the house is in such an utterly dilapidated condition that it would be impossible to render it fit for habitation then the owner is only to be compensated for the value of the land and of the materials on it.

With such stipulations it should be possible to reduce the compensation to be given to reasonable proportions. But property acquired under this Part I. of the Act has to be re-sold within ten years unless the Secretary of State shall otherwise decide. Part II. of the Act has for purpose to consolidate and amend Torrens's Acts of 1868 and 1882. The Local Government Board and the Secretary of State are to supervise and confirm schemes carried out under this part of the Act. It deals with individual dwellings and obstructive buildings rather than with large areas. Both district authorities and the County Council may take action and they may close a house as unfit for habitation. If this does not suffice they may, having obtained a magistrate's order, proceed to demolish the house. A house that merely obstructs ventilation may also be removed, and in that case the owner may, if he chooses, retain the land, but then he is only compensated for the building. The Local Government Board decides what provision, if any, must be made for re-housing the persons disturbed, but the question of re-housing is not so urgent, as this part of the Act can only be applied to a few houses. The rules in regard to compensation are the same as under Part I., excepting that deductions may be made if the improvements to be effected increase the value of other property held by the same owner. Under Part II., as under Part I., the land acquired must be sold within ten years unless otherwise decided by the Secretary of State; and he also determines what proportion of the cost shall be paid by the local authority and what by the County Council. To carry out such schemes the County Council has borrowing powers and may lend borrowed money to the district authority.

We now come to the much-discussed Part III., which seeks to amend and consolidate the Labouring Classes Lodging Houses Acts of 1851 to 1867. It first extends the meaning of the terms used so as to include a cottage with a garden of not more than half an acre, if the ground value does not exceed £3 per annum. Power is given for compulsory purchase of land, for the erection of lodging-houses, for fitting and furnishing the same, but the scheme for such purchase must be made public and the petitions in favour and against it submitted to the Secretary of State who may dismiss them or order further inquiries to be made. Then a provisional order sanctioning the compulsory acquisition of the lands may be issued, but it must be served on all concerned and confirmed by an Act of Parliament. If sanctioned the compensation to be paid is settled according to the Lands Clauses Consolidation Acts of 1845, 1860, 1869, and the special clauses of Parts I. and II. of the present Act. But the most salient feature of Part III. is that it confers no power to sell or lease the land purchased under this part of the Act; therefore, the Council was itself obliged to erect, manage, and let the lodgings or tenements to be built on the land. The land could only be sold when other land better suited for the purpose could be purchased with the price realised. Further, if lodging-houses have been open for seven years or more and have become unnecessary or too expensive they may be sold if the Secretary of State approves. The borrowing powers are the same as under Part I. and various kinds of corporations, trusts, &c., may borrow and various public bodies may lend money for the erection of working-class dwellings. On paper this Act, and especially Part III., gives promise of prompt reform; in practice its application has been found cumbersome and expensive. It is the question of compensation which, in spite of amendments and modifications, continues to occasion wearisome, prolonged, and expensive litigation.

The next legislative enactment was the Public Health (London) Act of 1891, giving effect to many of the recommendations made by the Royal Commission of 1884. It emphasises the duty of the district authorities to inspect and abate nuisances and to prevent overcrowding. Provision is made for petty sessional courts to deal summarily with such cases by means of prohibition and closing orders; and where two convictions for overcrowding have occurred within three months the court may order the house to be closed for such time as it may deem necessary. The borough councils must now fix what number of persons may occupy each room in a house let in lodgings or occupied by the members of more than one family, and must provide for the separation of the sexes, for the registration of houses so let or occupied, for the inspection of such houses, for their proper drainage, cleanliness, and ventilation, for the cleansing and lime-washing at stated intervals, and for the taking of proper precautions in case of any infectious disease. If the borough councils fail to carry out these regulations the County Council may take action, and the expenses of such action may be recovered by the County Council from the borough council which has neglected its duty. Or, again, the County Council may complain to the Local Government Board if a borough council is neglectful and the Local Government Board may by writ of mandamus force the borough council to take the necessary measures. Here again, if written laws were of themselves able to alter social and economical conditions, it would be thought that, in the face of such stringent enactments, insanitary dwellings and overcrowding would vanish away as if by magic; and yet all those who are personally acquainted with the conditions under which the London poor live are painfully aware how far we are from attaining any such ideal conditions.

The London Building Acts of 1894 and 1898 regulate the amount of open space that must be provided in all new streets both in front and at the back of the houses and this in proportion to the height of the houses. No house is to be built to a height of more than 80 feet, exclusive of

[1] Part I. was published in THE LANCET of Jan. 12th, 1901, p. 124.

the roof, without a special permission from the County Council, and in streets that are not more than 50 feet wide the houses must not be higher than the width of the street. But though this rule only applies to new thoroughfares it has a retrospective action with respect to working-class dwellings that are built within 20 feet of the centre of any highway. The latter must not exceed in height the width of the street whatever may be the date at which they were built. For streets laid out after 1894 the space behind the houses must have a width of at least half the height of the house. If it is a working-class dwelling this space behind may not be covered up; for other houses it may be covered to the height of 16 feet only.

In 1894 there was yet another Housing of the Working Classes Act. This was to extend the borrowing powers limited by Part II. of the Act of 1890 to the purchase money or compensation for properties acquired. But there are many other heavy incidental expenses, such as the preparing, sanctioning, and confirming a scheme, costs and fees, the laying out and sewering of new streets, &c., which had to be paid out of the current rates. The new Act sanctioned that these costs should be added to the sum for which borrowing powers were demanded.

Finally, we have the Housing of the Working Classes Act of 1900. The first important feature of this the last law enacted on the subject is that henceforth both the County Council and the borough councils of the metropolis may not only "establish or acquire lodging-houses for the working classes" within their own boundaries but may do so outside the limits of the county or the borough. Combining this with the organisation of cheap tramway or railway services it should be possible to relieve the congestion in central districts by removing a portion of the population to sites beyond the metropolitan area. Of course, this is only a partial solution of the difficulty applicable in some and not in all cases. Nor is the saving in expense so great as it seems at first sight. By removing a section of the population beyond the boundaries we reduce the rate-paying capacity of the inhabitants of the borough or county. While the local authority thus loses some of its financial resources the lodger or workman incurs extra expenses which counterbalance to some extent the economy he may make in paying cheaper rent. First, he has the cost of travelling backwards and forwards to his work—a cost which is as serious in time lost as in the outlay for his railway or tramway ticket. But what is perhaps more serious is the increased cost of food. The worker can no longer go home for his midday meal, and the money he has to pay at an eating-house would suffice, not only for his own food, but that of some members of his family. Then, again, the cost of provisions is generally higher in the outlying suburbs than in the central districts, where there is fiercer competition and more to choose. Nevertheless, for a section of the working-class it will prove an advantage to live beyond the metropolitan boundaries, but not for all.

The Act of 1900 also modified the critical Part III. of the Act of 1890. The County Council may now lease any land acquired under and for the purposes of Part III. if the lessee will undertake to carry out the Act—namely, to build and maintain on the land lodging-houses within the meaning of the Act. But in the lease provisions must be carefully inserted that such building must be kept in good repair, must be utilised exclusively as lodging-houses, and if the character of the buildings is in any way altered without the consent of the County Council then the lease lapses and the council have a right of re-entry. Therefore, the dwellings built on the land purchased under Part III. need no longer be erected and managed by the council, but this may be intrusted to anyone who will undertake to provide lodging-houses according to the conditions laid down. If a council pleads that it is not competent to act as the landlord of a number of poor and dissolute people it has the power by this new Act to lease the land to someone who is competent to do this somewhat unpleasant and rough work.

Of course, all this legislation was brought about in a great measure by the remonstrances which the County Council was induced to make in consequence of the great difficulties it had to encounter. No sooner had the council come into existence than it convoked a conference of all the local authorities to discuss the housing question. The first conclusions arrived at were that in building the council must keep in view what was likely to be the standard of sanitation in the future, so that their houses should not fall below that standard. In the long run it would prove cheaper to build well, but for the moment this would increase the difficulties. A number of regulations were drawn up in regard to the size of the rooms, the width of the stairs, the washhouse accommodation, &c. The staircase should be at least four feet wide, with a dado of hard glazed bricks. Closets should have doors and windows opening directly to the open air. No living room should be less than 144 square feet or bedroom less than 96 square feet, and at least nine feet high, and a dwelling-house should be at a distance of one and a half times the height of the nearest obstructing building. But it was soon found that such regulations involved too great a cost, and the height of the rooms was reduced to 8 feet 6 inches and the width of the stairs to 3 feet 6 inches.

By the time the County Council had been in office one year the number of insanitary areas brought under its notice amounted to 146. By the end of the year communications had been sent by the County Council to the vestries or district boards concerning 58 insanitary areas. About three-fourths of these areas brought to the notice of the County Council have now been improved and many houses have been demolished under Torrens's Acts. For larger areas 12 schemes were prepared by the vestries and district boards and four by the council, all of these under Part I. of the Housing of the Working Classes Act of 1890. But as it was found so very difficult to dispose of the land the council soon concluded it might be more expedient if it sought to fulfil the statutory obligations by itself erecting the dwellings. But to do this it was necessary to regulate the cost of building in accordance with the income likely to accrue. Hence the council passed in March, 1893, what is known as "the 3 per cent. resolution." This resolution laid down the principle that though the rents charged for the dwellings were not to exceed the general price prevailing in the neighbourhood, yet they were to suffice to pay all outgoings, interest, and sinking fund charges. To do this the design and plan of the buildings must be kept down so as not to involve too high a cost. Hence the modifications made as to the size of the rooms, width of staircases, &c., as mentioned above. Under the Treasury regulations the Council must provide a sinking fund that shall repay the capital cost of the land and building within 60 years. A cumulative annuity of 2½ per cent. is provided for this sinking fund and from 2½ to 3 per cent. more has to be paid as interest for the money that is borrowed. Therefore, the dwellings which the Council build must bring in rents enough to pay all cost of management, repairs, taxes, &c., and from 5 to 6 per cent. on the capital outlay to cover interest on borrowed money and provide for the sinking fund or amortisation. But when to meet these liabilities the County Council wanted to reduce the size of the rooms, &c., the Secretary of State objected. In 1894, before these objections were made, the Sonning-buildings, Boundary-street, were designed, with sculleries for the common use of several tenements but a separate w.c. for each tenement, and these are the cheapest buildings the council has erected. In 1897 the Secretary of State, judging from information received and experience acquired, concluded that the most suitable size for a living room was 160 square feet and 110 square feet for a bedroom, but if the tenement consisted of two bedrooms then they might measure 100 and 120 square feet respectively. This was accepted as the standard and rigorously enforced ever since. But other stipulations were also introduced at the same time. Thus an angle of 45 degrees of light has to be provided for all habitable rooms, and the number of persons using a staircase limited according to the size of the staircase. Several plans that had already been accepted had to be altered to meet these new exigencies. All this is admirable from the sanitary point of view, but it adds to the financial difficulties.

There is an anomaly in regard to this supervision of the plans of proposed dwellings. Those that are to be erected under Part I. must be submitted to the Secretary of State, but if action is taken under Part II. of the Act then the Local Government Board is the controlling authority and what may satisfy the one may not be approved by the other. Thus the Local Government Board is more particular in regard to thorough ventilation and rejected on this ground the plans of the East-end Dwelling Company for the buildings it proposed to erect in Ann-street, Poplar. Then in regard to Crawley-building, Brooke Market, Holborn, the closets were condemned as not sufficiently separated from the dwelling rooms. Wire gauze had to be substituted for the windows in the lobbies leading to the closets. Now it is found

that the tenants strive to block these openings by hanging up unsightly rags. Then the Local Government Board objected to staircases rising direct from the kitchen to the bedrooms above in cottages and also protested that the walls were not of sufficient thickness. Open staircases exposed to all weathers found favour with the Local Government Board, but were strongly objected to by the tenants, and a compromise had to be effected by putting windows in the lower part of the opening. Again, the tenants desired self-contained instead of associated tenements, which, of course, cost somewhat dearer. In regard to the size of the rooms the Local Government Board and the Home Office agree to the same standard, but the tenants do not agree and urge that every tenement should have at least one bedroom measuring 120 square feet instead of 110 square feet. On the other hand, the enormous cost of carrying out these schemes compelled the council, in the years 1898 and 1899, to revert to their minimum standard of 144 square feet for living rooms and 96 square feet for bedrooms. Thus does the balance fluctuate, weighted down at one time by sanitary exigencies and at another by financial restrictions. Evidently the key to the solution of the difficulty is to be found in the financial side of the problem.

THE REPORTS OF THE WATER EXAMINER TO THE LOCAL GOVERNMENT BOARD ON THE METROPOLITAN WATER-SUPPLY.

IN an annotation which appeared in THE LANCET some months ago[1] on the monthly reports of the Water Examiner to the Local Government Board it was pointed out that the chemical examinations of the water made by the analyst appointed by the Board were less numerous than the importance of the matter demanded. At that time one examination per month was made of one specimen only of the water supplied by each company. We are glad to be able to record the fact that a larger number of specimens are now examined. The Water Examiner to the Local Government Board at length considers it desirable that the number of samples should be increased and that the places from which they are drawn should be more widely distributed over the areas supplied by the individual companies. During the months of August and September, 1900, from 12 to 14 samples of water were taken from the mains of each company. The examination of these samples was, however, confined to the estimation of the amount at two temperatures of oxygen consumed (which is taken as the measure of organic pollution), the amount of albuminoid ammonia (which is taken as the measure of nitrogenous organic pollution), and the degree of turbidity (which is taken as the indication of efficiency of filtration or of "disturbances in the mains"). The usual monthly analyses of one sample of each water supplied by each company has also been supplemented by like determinations as to the oxygen consumed and the amount of albuminoid ammonia present.

We recommend that an examination of the Thames supply of the East London Company be made daily, at any rate during periods at which the Thames is at flood. No arrangements are made at the Thames station of the East London Company for the purification of water by sedimentation. The Thames water which is here filtered is mixed with some well water pumped at the filtering station, and this mixed supply is pumped to one of the reservoirs of the East London Company. This reservoir is also supplied by water from the Lee Bridge works of the company. It is therefore advisable that an examination should be made of the water as it is drawn from the filter-beds of the company at the Thames station. Most of the monthly reports of the Water Examiner state that samples collected at the works of the companies were efficiently filtered, but it is not stated that these results were arrived at by the analyst appointed by the Local Government Board, nor is there any indication that any special attention has been given to a determination of the effects of filtration without previous sedimentation of the Thames water distributed by the East London Company.

During the months of August, September, October, and November the condition of the natural Thames water was good throughout. The flow of the river was, during the greater part of the time, below the average summer level, and the rainfall during the period was small. Dr. T. E. Thorpe, F.R.S., the analyst appointed by the Local Government Board, reported that a sample drawn from the mains of the Lambeth Company during the month of August contained the highest proportion of organic carbon, and that the water supplied by the same company exhibited the deepest average tint of brown. Taking the filtering area of the West Middlesex Company as the normal it may be noted that a corresponding area of the Lambeth Company is little more than half of what it should be; the filtering area per 1,000,000 gallons in the case of the West Middlesex Company is 0·88 acre, that of the Lambeth Company is 0·48 acre. It may also be pointed out that the average rate of filtration is much greater in the case of the Lambeth Company than in that of the West Middlesex Company. The average rate of filtration per square foot per hour in the case of the West Middlesex Company during the month of August was 1·25 gallons and that of the Lambeth Company 2·20 gallons. The reserve capacity of the Lambeth Company also compares very disadvantageously with that of the West Middlesex Company. The capacities of the reservoirs for unfiltered water possessed by the West Middlesex Company are capable of holding a supply sufficient for the wants of the company for 18·5 days, but the capacities of the reservoirs of the Lambeth Company are sufficient only to contain an amount of water for the supply of their customers for five days.

During the month of September Dr. Thorpe examined 96 samples of the water supplied by the various companies, and the result showed that the amount of oxygen consumed was greatest in the case of the Lambeth Company; the Chelsea and Southwark and Vauxhall companies contained the greatest amount of albuminoid ammonia; and the water supplied by the Lambeth Company exhibited the deepest average tint of brown. During the month of October of 14 samples of the Grand Junction Company's water eight were clear and four—which were drawn from a stand-pipe at Shepherd's Bush-green—were distinctly opalescent and contained finely divided oxide of iron which the analyst believed was derived from the mains. The sample taken from the mains of the Grand Junction Company contained the highest proportion of organic carbon; the water of the Lambeth Company exhibited the highest average tint of brown. The Grand Junction Company possesses a smaller relative reservoir capacity than any other company; it is even smaller than that of the Lambeth Company, and is sufficient only to supply the wants of the company for 2·9 days. The Water Examiner points out that the Grand Junction Company has the means during floods of pumping water from the gravel beds adjoining the Thames, and "this is practically equivalent to an addition to their storage reservoirs." There is no statement in the report, however, as to the quantity of water which is in fact derived from the gravel beds, nor is any estimate given as to what amount of reservoir capacity this gravel water is practically equivalent to. These are points it would be interesting to know.

During the month of November the samples of water supplied by the Chelsea, Southwark and Vauxhall, New River, and East London companies were clear and that of the Grand Junction Company was also clear, except a specimen taken from a standpipe at Shepherd's Bush which was turbid. The engineer of the company explained that in his opinion the turbidity was caused by the fact that the standpipe was near to the dead end of a main, and he further stated that the defect had been remedied. It is not stated by what means this was done. The water supplied by the Grand Junction Company again contained the highest proportional amount of organic carbon; the water of the Lambeth Company exhibited the deepest average tint of brown. The amount of organic matter in the supplies of all the Thames companies showed a slight increase over that found during the previous month and the greatest increase was noted in the case of the Grand Junction Company.

The water supplied by the Kent Company during the whole period under review was, as usual, of excellent quality.

[1] THE LANCET, Sept. 8th, 1900, p. 748.

IT has been resolved by the Whitechapel Board of Guardians to convene a conference on the question of overcrowding.

THE BATTLE OF THE CLUBS.

ROTHERHAM DISTRICT.

THE old difficulties between friendly societies and their medical officers are assuming an acute form in the Rotherham district. The medical men concerned gave the clubs notice that after March 1st of the current year the fees for adults and juveniles belonging to friendly societies would be the same—viz., 1*s* 3*d*. per quarter or 5*s*. per annum. Previously the rate for adults had been 4*s*. per annum and for juveniles 2*s*. per annum. In answer to this the secretaries of the different lodges met and it was decided to form a medical aid association so as to be independent of the local medical men. We notice that the *Rotherham Express* states that the circular which was issued convening the meeting of secretaries referred to the extension of assistance to "wives, children, fathers, mothers, nephews, and nieces." Even the *Rotherham Express*, which obviously sides with the friendly societies, admits that this "is enlarging their borders with a vengeance." The present medical officers ground their request upon the well-known facts that their remuneration is upon the same scale as formerly, while against this wages have gone up and the cost of drugs, instruments, and dressings has also increased. Living is more expensive than formerly, while in addition no unqualified assistant may be employed, and the remuneration of qualified men acting as assistants has naturally increased. We do not in the least blame working men for trying to get medical attendance as cheaply as they can, but it is inconsistent of those men who are always agitating for and getting a rise in wages to object so strongly and selfishly to raise the wages of those whom they employ. A miner or an ironfounder undoubtedly works hard, but when he has finished his shift it is finished. Now a medical man's work is never done; for him there is no eight hours' day. At any time of the day or night he is liable to be called upon—it may be for something trivial, it may be for some disease or injury which may be irremediable if not promptly treated. 5*s*. per annum is less than 1½*d*. a week—not a very large sum for a man to spare who is getting good wages, as miners do, and very many of the members of the clubs concerned are miners whose wages have gone up, or will have after February, 60 per cent. in the last 12 years. The only thing to do unless the clubs should give way is for the medical men concerned to organise themselves. How organisation succeeds is very well shown by what happened at Cork and other places, accounts of which will be found in "The Battle of the Clubs" by our Special Commissioner.

CHESTERFIELD DISTRICT.

The club difficulty has also come to a head in the Chesterfield district where the eight medical men attached to a field club have demanded a rise of 1*s*. per member per annum, thus raising the yearly subscription of members from 4*s*. to 5*s*. per annum. At the quarterly meeting of the British United Order of Oddfellows the question came up and a proposal was made that the lodges should affiliate and take united action, but apparently no definite course of action was decided upon.

ASYLUM REPORTS.

Glasgow Parish, Govan and Lanark District Asylum, Kirklands (*Report for the year ending April 30th, 1900*).—The average number of patients resident during the year was 200 and comprised 105 males and 95 females. The admissions during the year amounted to 59—viz., 32 males and 27 females. Of these one male and four female patients were not first admissions. Dr. James H. Skeen, the medical superintendent, states in his report that the admission rate for the year has been higher than it was for the previous two years. The bodily health of those admitted was fairly good, though as usual there were several patients much broken down in health. "Many were suffering from severe illness and one or two from nothing less than brutal ill-usage in their own homes." The mental ailments of those admitted included a large number of cases the chance of recovery of which was practically *nil*, 33 per cent. of the total admissions belonging to this hopeless class. Among the causes of insanity in the admissions alcohol holds the first place, next in order of frequency come brain diseases, childbirth, and nursing and domestic troubles. The number of patients discharged as recovered during the year amounted to 23, or 11·5 per cent. of the average number resident. The proportion of recoveries has not been quite up to the average of the past 19 years. The number of deaths in the year amounted to 11, or 5·5 per cent. of the average number resident, and was one of the lowest numbers on record. Of the deaths one was due to old age, one to abdominal cancer, one to renal disease, one to cerebral hæmorrhage, two were due to epilepsy, and two to pulmonary phthisis. No serious casualty occurred during the year. One patient, a female, while out on probation in the care of her friends escaped after providing herself with male attire. She made her way to Dumbarton and worked there as a baker's lad for three weeks, when her sex was discovered. She then disappeared from there and made her way to Bothwell where she worked as a baker's boy. She was then discovered and taken into the care of philanthropic people and was understood to be doing well. A severe epidemic of influenza visited the institution in the spring of 1900. Luckily its duration was brief, but while it lasted it caused much inconvenience, as upwards of 50 patients and about 20 of the staff were confined to bed at one time. All made good recoveries except one, a female patient, who died. Among the long-felt wants are better sick-room accommodation, a better laundry, and houses for married attendants. There is an urgent need for water-cocks, two in front and two at the back of the building, for use in case of fire. The Commissioners in Lunacy state in their report that the case-books and registers were found to be carefully and correctly kept, and that the wards and dormitories were clean and in good order. The register of restraint and seclusion contained no entry for the year.

London County Asylum, Colney Hatch (*Report for the year ending March 31st, 1900*).—The average number of patients resident during the year was 2543, and comprised 918 males and 1625 females. The admissions during the year amounted to 591 and of these 234 patients were males and 357 were females. Of these 126 (comprising 37 males and 89 females) were not first admissions. Dr. W. J. Seward, the medical superintendent, states in his report that the total number of admissions was 103 in excess of the number in the previous year. Among the admissions were 50 patients suffering from epilepsy and 40 from general paralysis, 35 of the 40 being males. 61 patients were transfers from other asylums and nine were criminal lunatics admitted from prison. As regards the causes of insanity among the patients admitted hereditary tendencies were ascertained to exist in 27 per cent. of the cases, 17 per cent. (among the men 21 per cent.) were known to be of intemperate habits, and 29 per cent. had been under treatment for previous attacks. The number of patients admitted over 70 years of age was 31. Among the patients admitted were 22 boys, and it is pointed out that it would be "very desirable that some special accommodation should be provided for these cases, where they could be kept apart from the adult patients." The number of Jewish patients admitted was 69, the majority of them being Russians or Poles. In the previous year the number of Jewish patients admitted was 86. The number of patients discharged as recovered during the year was 245—viz., 70 males and 175 females, or 9·6 per cent. of the average number resident. "This is the highest recovery-rate of the last five years, and as regards female patients has only been exceeded on one occasion since the opening of the asylum." Of the 119 patients who were discharged unrecovered or removed, 25 were sent to the metropolitan district asylums, 72 were transferred to other asylums, two were removed to workhouses, and 19 were discharged to the care of their friends. The deaths during the year amounted to 240, or 109 males and 131 females, being at the rate of 9·4 per cent., of the average number resident. "This is a slightly higher rate than that of the last few years." Of the deaths four were due to influenza, three to renal disease, four to intestinal obstruction, one to enteric fever, nine to cancer, 10 to pneumonia, 12 to cardiac disease, 15 to colitis, 20 to mania and melancholia, 21 to senile decay, 23 to epilepsy, 23 to pulmonary phthisis, 32 to chronic cerebral disease, and 42 to general paralysis of the insane. Post-mortem examinations were made on 204 bodies. Inquests were held in three cases—viz., on a female patient who sustained an injury to the spine from the fall of the branch of an elm tree and died some months later, on a

male epileptic who died from asphyxia due to the impaction of a plum-stone in the trachea, and on a male patient who was assaulted by a fellow-patient and sustained fractures of several ribs and other injuries. The epidemics included colitis (in which 18 of the cases ended fatally), enteric fever (nine cases, two of which ended fatally), and influenza. The serious prevalence of phthisis and the risk of its spread among the asylum population are recognised, and the expediency of isolating tuberculous patients is pointed out. A profit of £1706 13s. is shown in the accounts of the farm, which is the highest ever recorded in the history of the asylum. Alterations in the wards have been made at a cost of £3025. The expenditure on repairs and alterations amounted to £10,537.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

A QUARTERLY meeting of the Council of the College was held on Jan. 10th, Sir WILLIAM MAC CORMAC, Bart., K.C.V.O., the President, being in the chair.

The Council elected Mr. George Henry Makins a member of the Court of Examiners.

The Council removed from the list of Members a Member who had been found guilty of disgraceful conduct in a professional respect.

In reply to a request from the Honorary Secretary of the Scottish History and Archæology Committee of the Glasgow International Exhibition the Council left it to the President and the Vice-Presidents to decide as to which of the memorials illustrative of Hunter's life should be lent for the purposes of the exhibition.

A letter was read from the widow of Professor Albert, Honorary F.R.C.S. Eng., of Vienna, thanking the Council for their sympathy with her in the loss of her husband.

The PRESIDENT stated that he had received a letter from Dr. G. Mondan of 27, Rue Jarente, Lyons, stating that a committee had been formed to collect a fund for erecting a public monument to the late Professor Ollier, Honorary F.R.C.S. Eng., and inviting Fellows and Members of the College to subscribe.

A letter was read from the Registrar of the General Medical Council forwarding a copy of the resolutions and new rules in regard to public health diplomas adopted by the Council on Dec. 5th, 1900.—They were referred to the Committee of Management.

A letter was read from Mr. Thomas Bryant reporting the proceedings of the General Medical Council at their late session.—The thanks of the Council were given to Mr. Bryant for his services as the representative of the College on the General Medical Council.

Inasmuch as the Hunterian Oration is to be delivered on Feb. 14th the next meeting of the Council will be held on Feb. 7th.

Public Health and Poor Law.

LOCAL GOVERNMENT DEPARTMENT.

REPORTS OF INSPECTORS OF THE MEDICAL DEPARTMENT OF THE LOCAL GOVERNMENT BOARD.

On the General Sanitary Circumstances of the Stroud Rural and Nailsworth Urban Districts, and on Administration by the respective District Councils, by Dr. F. St. GEORGE MIVART.[1]—Stroud rural district surrounds the town of Stroud in Gloucestershire and comprises a large portion of the Cotswold hills and of the valleys which intersect them, the principal being the Chalford valley, at the mouth of which Stroud is situated. The population is large, somewhere about 30,000, consisting mainly of persons employed at numerous mills which have been established along the streams in this district. These are chiefly woollen and dying mills, dependent on the streams for water-power and for convenient disposal of trade refuse. Dr. Mivart describes the dwellings as usually substantial in structure, but in many places back-to-back houses, or, on the hillsides, "back-to-earth" houses are undesirably common. Action under the Housing of the Working Classes Act seemed needed in certain cases owing to extensive dilapidation and dampness. Notwithstanding the abundance of small streams and springs in the district, pure water-supplies are usually lacking. About one-fifth of the houses in the rural district are served by the Stroud Waterworks Company; elsewhere the supply is obtained, for individual dwellings or for small groups of houses, from wells, springs, and streams. The wells often receive directly the drainage of the surface of polluted soil above them, or for other causes the purity of their water is open to much suspicion. Natural springs, issuing from the lower oolites where these strata rest upon lias, are seldom impounded for local supplies, as they might easily be at trivial cost. On the contrary, they are allowed to run away as streamlets, the water of which is often utilised by villages only after it has been subject to divers opportunities of dangerous pollution. Evidently, as Dr. Mivart indicates, much good could be done by a local authority which would tackle the question of local water-supplies in a business-like spirit. Much greater difficulty attaches to dealing with the question of pollution of streams and rivers hereabouts. Contamination arises partly from sewage of villages, partly from houses on the banks of streams which frequently have closets built out over the water's edge, but mainly from manufacturing refuse. "Speaking generally, contaminating chemical matters are in such large quantity as to completely obscure the presence of sewage matter." So considerable are the accumulations due to manufacturing refuse which take place in the streams that their banks have annually to be "mudded"—that is to say, the mill-owners, individually or in combination, have to cleanse the banks by detaching the accumulated filth—a proceeding which creates a serious nuisance. The mill-owners maintain that unless they can discharge their untreated trade refuse into the water-courses "the closure of their mills would be inevitable." To require the manufacturer to return pure water to the stream might very probably mean imposing on him a heavier burden than he could bear. But that a great deal, short of perfection, can be done at a not ruinous cost, has been shown in Lancashire and Yorkshire in consequence of the action of river boards, and a reasonable minimum of preliminary treatment might, one would imagine, be exacted in Gloucestershire without much hardship. When we read that at every factory visited by Dr. Mivart the privies for workpeople were placed overhanging the streams, it would seem that here, at any rate, manufacturers might have saved themselves ultimate expense by the use of a little foresight. Pollution of this sort can hardly be represented as inevitable. Dr. Mivart notes that it is common in this district for urine to be stored in large tubs in the neighbourhood of dwellings and to sell it to cloth mills where it is used for soaking freshly-made cloth. He points to sundry matters, such as sewage disposal of villages and disposal of house refuse, which appear to be much in need of attention by the local authority. It is interesting to note that a method of disposal of excreta often adopted is to cast such matters into "lissens," or fissures in the Great Oolite strata, a practice sometimes clearly entailing risk to water-supplies. Cow-sheds in Stroud rural district appear to be kept in a particularly unwholesome and uncleanly condition. A variety of insanitary circumstances in the urban district of Nailsworth, which forms, as it were, an island in the Stroud rural district, are also detailed, and Dr. Mivart adds certain administrative recommendations in regard of both sanitary areas.

VITAL STATISTICS.

HEALTH OF ENGLISH TOWNS.

IN 33 of the largest English towns 6577 births and 4442 deaths were registered during the week ending Jan. 12th. The annual rate of mortality in these towns, which had been 16·1, 16·9, and 17·5 per 1000 in the three preceding weeks, had further risen to 19·6 per 1000 last week. In London the death-rate was also 19·6 per 1000, which was also the average rate in the 32 large provincial towns. The lowest death-rates in these towns were 12·8 in Huddersfield, 13·7 in Halifax, 13·8 in Derby, and 13·9 in Croydon; the highest rates were 22·7 in Nottingham, 22·8 in

Manchester, 24·9 in Liverpool, and 27·3 in Salford. The 4442 deaths in these towns last week included 389 which were referred to the principal zymotic diseases, against 351, 334, and 323 in the three preceding weeks; of these 110 resulted from whooping-cough, 81 from diphtheria, 66 from measles, 56 from diarrhœa, 41 from "fever" (principally enteric), and 35 from scarlet fever. The lowest death-rates from these diseases last week occurred in Wolverhampton, Halifax, Gateshead, and Newcastle, and the highest rates in Nottingham, Salford, Blackburn, and Preston. The greatest proportional mortality from measles occurred in Liverpool; from whooping-cough in Salford, Bristol, Nottingham, Birkenhead, and Preston; and from diarrhœa in Swansea and Blackburn. The mortality from scarlet fever and from "fever" showed no marked excess in any of the large towns last week The 81 deaths from diphtheria included 25 in London, nine in Liverpool, eight in Sheffield, and six in West Ham. No fatal case of small-pox was registered last week in any of the 33 towns, and only one small-pox patient remained under treatment on Saturday last, Jan. 12th, in the Metropolitan Asylums Hospitals. The number of scarlet fever patients in these hospitals and in the London Fever Hospital at the end of the week was 2277, against 2535 and 2390 on the two preceding Saturdays; 156 new cases were admitted during the week, against 218, 167, and 163 in the three preceding weeks. The deaths referred to diseases of the respiratory organs in London, which had been 306, 325, and 330 in the three preceding weeks, further rose last week to 391, but were 338 below the corrected average weekly number. The causes of 63, or 1·4 per cent., of the deaths in the 33 towns last week were not certified either by a registered medical practitioner or by a coroner. All the causes of death were duly certified in West Ham, Nottingham, Salford, Bradford, and in 12 other smaller towns; the largest proportions of uncertified deaths were registered in Liverpool, Blackburn, Sheffield, and Gateshead.

HEALTH OF SCOTCH TOWNS.

The annual rate of mortality in the eight Scotch towns, which had been 20·6 and 19·2 per 1000 in the two preceding weeks, rose again to 21·9 during the week ending Jan. 12th, and showed an excess of 2·3 per 1000 over the death-rate during the same period in the 33 large English towns. The rates in the eight Scotch towns ranged from 16·3 in Paisley and 18·1 in Greenock to 22·6 in Glasgow and 30·3 in Perth. The 685 deaths in these towns included 49 which were referred to whooping-cough, 22 to diarrhœa, 12 to measles, eight to diphtheria, six to scarlet fever, two to small-pox, and two to "fever." In all, 101 deaths resulted from these principal zymotic diseases, against 87 and 76 in the two preceding weeks. These 101 deaths were equal to an annual rate of 3·2 per 1000, which was 1·5 above the mean rate last week from the same diseases in the 33 large English towns. The fatal cases of whooping-cough, which had been 33 and 29 in the two preceding weeks, rose again last week to 49, of which 36 occurred in Glasgow, six in Dundee, four in Edinburgh, and two in Greenock. The deaths from diarrhœa, which had been 15 18, and 22 in the three preceding weeks, were again 22 last week, and included 12 in Glasgow, four in Dundee, and four in Aberdeen. The fatal cases of measles, which had been 12 and 15 in the two preceding weeks, declined again last week to 12, of which five were registered in Edinburgh and five in Aberdeen. The deaths from diphtheria, which had been nine and three in the two preceding weeks, rose again to eight last week, and included four in Edinburgh, two in Glasgow, and two in Aberdeen. The fatal cases of scarlet fever, which had declined from nine to two in the five preceding weeks, rose again last week to six, of which three were recorded in Glasgow, where the two deaths from small-pox and the two fatal cases of "fever" were also registered. The deaths referred to diseases of the respiratory organs in these towns, which had been 121 and 105 in the two preceding weeks, rose again last week to 123, but were 80 below the number in the corresponding period of last year. The causes of 25, or nearly 4 per cent., of the deaths in these eight towns last week were not certified.

HEALTH OF DUBLIN.

The death-rate in Dublin, which had been 21·5 and 29·4 per 1000 in the two preceding weeks, declined again to 28·3 during the week ending Jan. 12th. During the past four weeks the death-rate in the city has averaged 26·2 per 1000, the rate during the same period being 17·5 in London and 19·4 in Edinburgh. The 188 deaths belonging to Dublin registered during the week under notice were nine below the number recorded in the preceding week and included 18 which were referred to the principal zymotic diseases, against 12 and 23 in the two preceding weeks; of these, 10 resulted from whooping-cough, three from "fever," two from diphtheria, two from diarrhœa, and one from scarlet fever. These 18 deaths were equal to an annual rate of 2·7 per 1000, the zymotic death-rate during the same period being 1·5 in London and 2·4 in Edinburgh. The fatal cases of whooping-cough, which had been six, five, and 13 in the three preceding weeks, declined again to 10 last week. The deaths referred to "fever," which had been four, four, and three in the three preceding weeks, were again three last week. The two fatal cases of diphtheria showed a decline from the number in the preceding week. The 188 deaths in Dublin last week included 26 of children under one year of age and 59 of persons aged upwards of 60 years; the deaths of infants showed a marked decline, while those of elderly persons exceeded the number in the preceding week. Nine inquest cases and seven deaths from violence were registered during the week, and 56, or nearly a third, of the deaths occurred in public institutions. The causes of 10, or more than 5 per cent., of the deaths in the city last week were not certified.

THE SERVICES.

ROYAL NAVY MEDICAL SERVICE.

THE following appointments are notified:—Fleet Surgeons: H. L Crocker to the *Royal Arthur* and to the *Blake*, and A. W. May to the *Britannia*. Surgeons: A. R. H. Skey to the *Royal Arthur*, additional, and to the *Blake;* N. L. Smith to the *Renown;* A. H. H. Vizard to Plymouth Hospital; R. T. A. Levinge to the *Boscawen*, for the *Agincourt;* and R. C. Munday to the *Cambridge*.

ROYAL ARMY MEDICAL CORPS.

Lieutenant-Colonel Sir James R. A. Clark, Bart. (r.p.), is appointed to command the detachment of Militia Medical Staff Corps at Aldershot and also for duty at the Cambridge Hospital. Lieutenant Carr is appointed to the medical charge of troops at Ewshot Camp and Lieutenant Lauder to Deep Cut Camp, Frimley. Lieutenant E. Bennett goes to Longmoor and Borden Camps, Woolmer. Lieutenant J. E. Hodgson is posted to the Station Hospital, Western Heights, Dover. Colonel T. J. Gallwey, C.B., on return from active service in South Africa, has been reappointed to the medical charge of the Home District.

VOLUNTEER CORPS.

Artillery: 1st Fifeshire: Surgeon-Lieutenant J. C. G. Macnab to be Surgeon-Captain and to remain Supernumerary; Surgeon-Lieutenant A. Watson to be Surgeon-Captain. The Tynemouth (Western Division, Royal Garrison Artillery): Surgeon-Captain A. Duke resigns his commission. *Rifle:* 2nd Volunteer Battalion the King's (Liverpool Regiment): Surgeon-Major G. Westby to be Surgeon-Lieutenant-Colonel. 2nd Volunteer Battalion the East Yorkshire Regiment: Surgeon-Major A. T. Brand resigns his commission, with permission to retain his rank and to wear the uniform of the battalion on retirement. 1st Volunteer Battalion the Cheshire Regiment: Surgeon-Lieutenant J. B. Yeoman to be Surgeon-Captain.

TRANSVAAL WAR NOTES.

The hospital ship *Nubia* is returning to England with the following invalids on board: Civil Surgeons W. V. Eaves and H. C. Donald. Civil Surgeons C. Colin Campbell, S. L. Stephens, and W. Edwards are on their passage home in the same vessel.

Thirty-nine non-commissioned officers and men of the Royal Army Medical Corps have embarked at Southampton in the *Avoca* for South Africa.

The *Aurania* left for England on Jan. 8th, having on board Lieutenant-Colonel D F Franklin, R.A.M.C., Civil Surgeons B J. Collingwood. D. L. Griffiths, W. G. Sutherland, L. T. Whelan, and F Brinckwell.

Civil Surgeons J. G. Martin, A. W. Sanders, H. Hartley, N. E. Harding, and Major E. A. Burnside, R.A.M.C., have been discharged from hospital to duty.

Surgeon S. C. Godfrey, New Zealand M.I., has also been discharged to duty.

The members of the Ambulance Brigade attached to the Northampton Centre were entertained at a banquet at the Town Hall, Northampton, on Jan. 12th. Messages from the Queen and the Prince of Wales, congratulating the county of Northampton upon having furnished a large contingent for voluntary service of mercy in South Africa, were read.

THE ROYAL ARMY MEDICAL CORPS IN THE FIELD.

At the Garrison Gymnasium, Devonport, on Jan. 8th, Surgeon-General G. H. J. Evatt, principal medical officer of the Western District, in the presence of a large number of officers and non-commissioned officers, delivered an interesting lecture on the Organisation of the Royal Army Medical Corps in the Field. General Evatt said that a large amount of aid was wanted to make the Royal Army Medical Corps fit for the field, and the medical service was still very short-handed. He also stated that there was not a medical company of volunteers in the Western District, and he wanted a number of men to come forward from Plymouth and Devonport to form a volunteer company. At the conclusion of the lecture, on the motion of Colonel W. Clarke, a vote of thanks to General Evatt was unanimously passed.

THE BEARER DETACHMENT OF THE 2ND VOLUNTEER BATTALION (MANCHESTER REGIMENT).

The first annual dinner of the bearer detachment of the 2nd Volunteer Battalion (Manchester Regiment) was held in Manchester on Jan. 12th. Surgeon-Major G. H. Darwin presided, and among those present were Surgeon-Captain Westmacott, Surgeon-Lieutenant J. Ratcliff-Gaylard, and Dr. T. C. Railton. During the evening Surgeon-Major Darwin said that he ventured to think that they were on the eve of great changes in the medical as well as in the combatant services. He would make it compulsory for every combatant to pass through a course of ambulance duty, as being useful not only to the battalion, but also to themselves in time of need. A great deal had been done during the last 50 years in England in developing an ambulance system, and this had been further developed by the great service of the St. John Ambulance Association, which had sent upwards of 2000 men to the present war. The Volunteers had never abolished the old regimental system. After many years of struggling to make their bearer detachment a success he was prepared to advocate one of two things, either that they should have a separate medical staff company to each battalion, or that they should have a portion of the already formed Medical Staff Corps allotted to each battalion for practical purposes.

THE FEVER STATISTICS OF WAR.

On the occasion of the third anniversary dinner given at the Caledonian Club to General Ian Hamilton and other officers returned from South Africa, the Director-General of the Army Medical Service, made some remarks in connexion with the subject of the prevalence of enteric fever in modern warfare. Surgeon-General Jameson said that he owed the honour paid him that evening to the fact that he had the good fortune to hail from beyond the Tweed and to the further fact that he represented a department in the army burdened with many responsibilities. In every war during our own time the mortality from disease had been much greater than that from shot and shell. In the French war in Madagascar the mortality from disease was 32·2 per cent., while the mortality from wounds was *nil*. In Cuba the mortality from disease in 15 months was 40 per cent., irrespectively of the number sent home. Unfortunately, we had lost a great many men from disease in South Africa and the mortality from that cause was foreseen before the war. Of every 100 cases admitted to hospital in Ladysmith and Maritzburg during the year before the war 5½ per cent. were enteric cases. Inoculation was a great preventative and a man who had not been inoculated was more liable by six times to an attack of enteric fever than a man who had been inoculated. During the Franco-German war, while the Germans were surrounding Metz the mortality from enteric fever was nearly three times as great as in South Africa.

A SPECIAL CORRESPONDENT ON THE DEATH OF CIVIL SURGEON F. G. ENGELBACH.

In a graphic account of the Nooitgedacht reverse, after noticing the death in the hottest of the fight of Sergeant Read of the Scottish Rifles, attached to the Mounted Infantry, in circumstances of typical bravery, the special correspondent of the *Standard* gives the particulars of the case of Surgeon Engelbach in the following words: "The death of Surgeon Engelbach of the Yeomanry Hospital was also a typically brave one. Tending the wounded under heavy fire he was shot through the palm of the left hand and had just made a grim joke about now being handicapped in his work when in standing up to dress his wound he was killed by a bullet through the forehead."

HOSPITAL STOPPAGES.

The *Army and Navy Gazette* of Jan. 12th says that it is glad to learn that the question of hospital stoppages has again been under consideration, and that this time the War Office has been in a position to obtain justice for the soldier. The Treasury has been induced, owing to strong representations, our contemporary is informed, to amend the regulations on the subject to the extent of allowing power to general officers commanding districts to remit the whole of the stoppages due from soldiers under treatment for injuries received in the actual discharge of their military duties. This concession will be fully appreciated, and at the present moment seems particularly opportune.

HEALTH OF THE CHATHAM GARRISON.

Some important communications have recently passed between Vice-Admiral Sir William R. Kennedy, Commander-in-Chief at the Nore, and Major-General Sir Thomas Fraser, commanding the Thames district, with reference to the large number of cases of disease contracted by the men of the fleet and garrison at Chatham. A copy of the correspondence has been forwarded by the admiral to the Chatham Corporation who were asked if they could not take some steps in the matter. The corporation have referred the subject to a committee.

ASSASSINATION OF A MEDICAL OFFICER.

With reference to the murder of Captain Dudley Johnston, I.M.S., which we mentioned last week, a telegram from the correspondent of the *Times* at Lahore dated Jan. 12th states that the fanatic lay in wait at the entrance of the bazaar armed with a sword and a dagger to kill the first European he saw. On the entry of Captain Johnston the Ghazi rushed at him and stabbed him to death. The murderer then ran through the bazaar, but was pluckily caught by the bazaar jemadar. He was promptly tried and hanged.

THE VICTORIA CROSS.

The Queen has signified her intention of conferring the Victoria Cross upon Lieutenant E. T. Inkson, R.A.M.C., who on Feb. 24th, 1900, carried Second-Lieutenant Devenish (who was severely wounded and unable to walk) for three or four hundred yards under a very heavy fire to a place of safety. The ground over which Lieutenant Inkson had to move was much exposed, there being no cover available.

THE REPORT OF THE ROYAL COMMISSION ON THE SOUTH AFRICAN HOSPITALS.

Sir William Church, speaking at University College Colston Society dinner at Bristol on Jan. 15th, said that the report of the Royal Commission into the South African Hospitals had been completed and signed, and now only awaited acceptance by the Queen in order to be made public.

THE CRISIS IN CHINA.

The American hospital ship *Maine* has discharged at Southampton four officers and 138 rank and file patients. With the exception of 34 taken on board at Malta the invalids were from China. All the patients are now at Netley.

DEATHS IN THE SERVICES.

Surgeon-Lieutenant-Colonel Saunders Barton Haliday, I.M.S. (retired), in his fifty-eighth year, at his residence, Thicket-road, Anerley. He served in the Abyssinian war of 1867-68 (medal) and also in the Afghan war, 1878-79 (medal).

Major W. Babtie, V.C., R.A.M.C., the medical hero of Colenso, has just received the freedom of the Borough of Dumbarton.

THE Borough Council of Battersea have decided to borrow £985 for the purpose of erecting a post-mortem room, £2723 for a coroner's court, and £8825 towards providing new baths and washhouses.

Correspondence.

"Audi alteram partem."

"THE X RAYS IN SOUTH AFRICA."

To the Editors of THE LANCET.

SIRS,—As Mr. Hall-Edwards's paper on the above subject in THE LANCET of Jan. 12th is calculated to convey a wrong impression as to the steps taken by the War Office for the carrying out of x-ray work during the war I trust you will permit me to endeavour to correct it. During the three years previously to October, 1899, when I went to South Africa, I instructed all the young officers who passed through Netley in radiography and the methods of localisation of foreign bodies by this means, and the large majority of these officers I know to be capable of doing the work efficiently. Originally the intention of the War Office authorities was that x-ray work should be done by them, but it soon became evident that medical officers could not be spared for this important duty, as to make anything of it they had practically to devote all their time to it. The Surgeon-General of the Army, therefore, wired home recommending that experts in radiography should be sent out, and this was done. That these gentlemen were experts (without the note of interrogation which Mr. Hall-Edwards so frequently places after the word in his paper) is proved by the work they did during the war. I saw a large number of localisations accurately done by them, and I brought home with me an enormous number of negatives and prints of excellent quality taken by them which I hope I may be permitted to publish at some future time. Many of these skiagrams were taken for the localisation of bullets in the most difficult parts of the body—the head, chest, and pelvis—and were well done.

As regards the provision for x-ray work made by the War Office for the army in South Africa, every base and general hospital, each hospital ship, and some of the small stationary hospitals on the lines of communication took with them the army pattern x-ray apparatus made by Apps and Newton, which includes Mr. Mackenzie Davidson's localiser and an ample supply of plates and all other photographic materials. Care was taken that one or more of the officers already referred to as being familiar with x-ray work should form part of the *personnel* of these units on leaving England; but, as stated above, their services in this department had to be dispensed with. That Mr. Hall-Edwards succeeded where some of our experts failed is probable enough, but this fact hardly warrants him in so criticising the medical department of the War Office as to lead your readers to suppose that it took no interest in so important a modern surgical procedure as radiography and that it provided for its performance in the present campaign in but a very imperfect manner.

The x-ray department which Mr. Hall-Edwards recommends for the army is (and has been for some years) in existence here, and the methods of localisation and radiography are already being properly taught. The apparatus used here, as well as that sent to South Africa, had the approval of Mr. Mackenzie Davidson, a strong evidence for its correctness and completeness, as no surgeon or electrician has done as much as he has for the improvement and development of x-ray procedures. The present campaign is not the only one in which x-ray work has been done by officers of the Royal Army Medical Corps, as good results were also obtained in the last Soudan war. No one in these days is likely to neglect the advantages of radiography, and least of all the medical department of the War Office.—I am, Sirs, yours faithfully,

W. F. STEVENSON,
Colonel R.A.M.C.; Professor of Surgery, Army Medical School.
Netley, Jan. 14th, 1901.

"THE TEACHING OF ANÆSTHETICS."

To the Editors of THE LANCET.

SIRS,—It seems to me very undesirable that the important question of making anæsthetics a recognised part of the medical curriculum should at its present stage be hampered by side issues such as those which form the real essence of Lieutenant-Colonel Lawrie's letter in THE LANCET of Jan. 5th, p. 64. The point before the profession is whether the student should or should not be compelled to attend a course of instruction in the use of anæsthetics—not whether this or that anæsthetic should be chosen for routine use, or this or that system of anæsthetisation adopted. Up to the present time I have taken no part in the discussion which you, Sirs, by your leading article have so happily initiated, for I have been hoping that some prominent members of the profession would interest themselves in the movement and set the ball rolling by bringing their influence to bear upon the General Medical Council and examining bodies. I need hardly say, however, that the matter has my fullest sympathies. It is to my mind an extraordinary fact that at the commencement of the twentieth century it is possible for a medical man to enter practice without ever having attended a course of instruction in anæsthetics or handled an ether or chloroform inhaler. Surely the public ought to be protected against the risks attendant upon such a state of affairs. Pending the settlement of this question it is certainly a pity that Colonel Lawrie should, under the guise of supporting the movement, again stir up the muddy waters of the chloroform controversy; and were it not that the statements which he makes are likely to mislead the uninitiated they would certainly be most appropriately treated by the silence they deserve.

Colonel Lawrie attacks the present teaching of English anæsthetists and again urges the claims of chloroform. His letter is certainly not characterised by moderation in language. He is, naturally enough, disappointed at the verdict expressed by the scientific world upon the work of the Hyderabad Commission and his infelicitous strictures are perhaps excusable. But those of us who have spent the best part of our lives in the special study and practice of anæsthetics have a distinct duty to perform to the younger members of the profession when we see in print such misleading assertions as those contained in Colonel Lawrie's letter. The chloroform problem has, in fact, been solved both clinically and experimentally. Whilst there are numerous circumstances under which this anæsthetic is unquestionably preferable to all others, whilst skill in its administration almost abolishes its risks, whilst it is free from many of the disadvantages and even dangers of ether, the broad fact remains, that in the hands of *the average medical man* the last-named anæsthetic is less likely to destroy life than chloroform. It is for this reason that the London anæsthetists very properly advise those whom they instruct to select ether in preference to chloroform for the ordinary run of surgical cases. The margin of safety with this anæsthetic is a wide one—a point of great importance when we bear in mind the fact that the surgeon of to-day expects his patients to be kept, not, as Colonel Lawrie apparently keeps his patients, *moderately* anæsthetised, but profoundly narcotised—i.e., *beyond the point at which corneal reflex disappears.* Had we to instruct men who, like Colonel Lawrie, possess a special aptitude for anæsthetising, who are destined to practise under climatic conditions similar to those of Hyderabad, who when in practice will only have to assist surgeons with somewhat antiquated ideas as to what is meant by "anæsthesia," and who would be content to become and to be treated as mere dispensers under the "supreme command" of the surgeon—it is quite conceivable that some slight modification in the present teaching might be expedient. But most of the men passing through the hands of those who, under the present inadequate support of authority, do their best to instruct students are not thus specially gifted. Nor are they, as a rule, men who are about to enter practice in sunny Hyderabad. A large proportion of them, indeed, go into country practice in England, and possibly into cold and low-lying districts where the atmospheric conditions are not the most favourable for anæsthetising. Then, again, they are men who see in their hospital experience *true* surgical anæsthesia and who know that when they enter practice they themselves will be expected to produce for the surgeons whom they may meet a similarly profound state of insensibility. And lastly, they are men who, thanks to the courtesy of English surgeons, will be allowed a perfectly free hand in the choice and administration of the agent employed.

It is the duty of an instructor in anæsthetics primarily to consider the safety of the public, and in the discharge of this duty he is, I submit, bound to advise his students to employ that anæsthetic which, so far as available evidence goes, is least likely to destroy life. He must put aside convenience, simplicity, and personal bias.

Now what record has chloroform? I cannot within the compass of this letter even summarise the evidence against this anæsthetic, but it is perfectly conclusive. I may, however, refer to a somewhat interesting incident bearing upon the supposed safety of chloroform in the country north of the Tweed. A few years ago I had the honour to receive a deputation from an important Scotch hospital in which, so far as my memory serves me, no less than nine chloroform accidents had occurred in one year. I was asked to express an opinion as to the best form of ether inhaler. Colonel Lawrie would encourage the use of chloroform even for tooth extraction. But what is the record of this anæsthetic in dental surgery? Some years ago I thoroughly investigated this point, and I laid my results, in the form of a paper, before the British Dental Association. Curiously enough the annual meeting of this body was that year held in Edinburgh, and the facts and figures which I there brought forward were not disputed. I found that in 15 years (1880–1894 inclusive) no less than 37 deaths had been recorded as having occurred in Great Britain in connexion with anæsthesia for dental operations. Of these, 14 occurred in Scotland (12 chloroform deaths); 21 in England and Wales, excluding London (15 chloroform deaths); and two in London (no chloroform deaths). Now, according to the Census returns (average between 1881 and 1891) the population of Scotland was roughly 4,000 000; that of England and Wales (excluding London) was 23,250,000; and that of London was 4,250,000. From this it follows that during the 15 years ending 1894 the dental anæsthetic death-rate in Scotland was more than four times as great as that in England and Wales, and about seven times as great as that in London. Had the rate in England and Wales been the same as in Scotland there would have been at our doors about 96 fatalities during this period; whereas, as my figures show, there were only 23. The explanation is obvious: it is that the Scotch death-rate was due to the use of chloroform. In London, where this anæsthetic is rarely if ever used in dental practice, the ratio of deaths to population was extremely small; in England and Wales (excluding London) where chloroform is used, but not to the extent which obtains in Scotland, the ratio was considerably higher; and in Scotland itself, where chloroform is the routine anæsthetic—at all events for all major dental operations—the ratio was very much higher. And yet, with facts and figures such as these we find Colonel Lawrie still endeavouring to inculcate a disregard for the risks of chloroform If it were necessary further to strengthen the above results one might add that it is quite possible, if not probable, that many more deaths than those of which I was able to find records actually took place in Scotland during the 15 years referred to, for there are, as is well known, no coroners' inquests in Scotland, so that chloroform accidents often escape notice.

I am, Sirs, yours faithfully,

Queen Anne-street, W., Jan. 14th, 1901. FREDERIC HEWITT.

WEAK POINTS IN THE EXAMINATION SYSTEM.

To the Editors of THE LANCET.

SIRS,—There can be little doubt among those who have had much experience in teaching and examining medical students that in a small percentage of cases at examinations the candidate's fitness to pass is not fully appreciated. There can, I think, be less doubt that the teacher is able to gauge a student's capabilities and knowledge more accurately than an examiner can, and yet, under the present system of medical examination, no use is made of the information which teachers could so easily give. Every examiner must remember cases in which a candidate has almost deserved the minimum mark to pass, and the doubt has arisen as to whether he is a hard-working man who has failed to do himself justice or one who has crammed up just sufficient transitory knowledge to get near the pass limit. In my opinion it would be a great assistance to examiners in their attempts to be absolutely fair if teachers were invited to send in a confidential report of the industry and capacity of each student. These reports need be used in doubtful cases only, and their existence would tend to make men try to win their teacher's good opinion by steady systematic work rather than to get up a certain part of their subject from books and trust to luck that the examiner may not pitch upon the part of which they are ignorant. Teachers may, I think, be trusted to act honourably by the examining boards. They are the people from whom examiners are drawn and during the time of their examinership implicit faith is reposed in them, although their opportunities of giving an unfair advantage to their own students are very great. If any of my fellow teachers will spare time to discuss this matter I think good will come of it, for as a teacher I know that medical examinations, though fair enough on the whole, are capable of some little improvement.

I am, Sirs, yours faithfully,

F. G. PARSONS.

Anatomical Department, St. Thomas's Hospital

"ARSENIC AND AERATED WATERS."

To the Editors of THE LANCET.

SIRS,—Dr. Bampton has raised a most important point in reference to the preparation of mineral waters from the action of sulphuric acid containing compounds of arsenium and derived from arsenical pyrites. The impure acid, it is interesting to note, may be used with impunity if certain conditions do not arise. The reaction occurring between arsenical vitriol and a carbonate of calcium or sodium in a leaden generator may be expressed by the simple formula—

$$(1)\ CaCO_3 + H_2SO_4 = CaSO_4 + H_2O + CO_2\ (gas),$$

the arsenical compounds, so far as manufacturing purposes are concerned, remaining latent and harmless. If, however, a scrap of iron, such as a nail or a portion of zinc, finds its way into the generating vessel the organism is converted into the guise of the death-dealing gas "arsine" (AsH_3), which is pumped with the carbon dioxide into the cylinder and is taken thence under high pressure (from 120 to 180 pounds) on the square inch and forced into bottles or syphons. The chemical changes that occur may be expressed as follows:—

$$(1)\ 3Fe + 3H_2SO_4 = 3FeSO_4 + 3H_2$$
$$(2)\ 3H_2 + H_3AsO_3 = 3H_2O + AsH_3\ (gas).$$

In this reaction the nascent hydrogen produced by the action of the "sulphuric acid" upon the "iron" reduces the "arsenious acid" to the condition of arsine (AsH_3) (gas). It is unnecessary for me to point out what terrible effects such a catastrophe would produce and the warning that all those who are concerned in the manufacture of mineral waters should take to avoid the use of any vitriol not guaranteed free from arsenical compounds in their processes.

I am, Sirs, yours faithfully,

NINIAN MCI. FALKINER, M.D. Dub.

Dublin, Jan. 9th, 1901.

*** The arsenical contamination of aerated waters in the way suggested by our correspondent is, we think, a remote probability. The carbonic acid gas contained in steel tubes is not usually prepared from acid and whiting. Most manufacturers test the purity of the gas by exposing it to potash solution. Pure CO_2 would be completely absorbed but not hydrogen or arseniuretted hydrogen. Lastly, aeration is very unsatisfactory when insoluble gaseous impurities are present.—ED. L.

"LET US NOW PRAISE FAMOUS MEN."

To the Editors of THE LANCET.

SIRS,—Your eloquent appeal in a leading article last week contains incidentally a pathetic reference to the grave of Sir Thomas Browne; the well-known passage beginning, "There is nothing strictly immortal but immortality," may, perhaps, not unfittingly be recalled to the memories of your readers. I subjoin the lines referred to.

I am Sirs, yours faithfully,

Worthing, Jan. 13th, 1901. GEORGE PINDER.

SIR THOMAS BROWNE, *Hydriotaphia, Chap. V.*

There is nothing strictly immortal but immortality. Whatever hath no beginning, may be confident of no end; which is the peculiar of that necessary essence that cannot destroy itself; and the highest strain of omnipotency, to be so powerfully constituted as not to suffer even from the power of itself: all others have a dependent being and within the reach of destruction. But the sufficiency of Christian immortality frustrates all earthly glory, and the quality of either state after death makes a folly of posthumous memory. God who can only destroy our souls, and hath assured our resurrection, either of our bodies or names, hath directly promised no duration. Wherein there is so much of chance that the boldest expectants have found

unhappy frustration: and to hold long subsistence seems but a scape in oblivion. But man is a noble animal, splendid in ashes, and pompous in the grave, solemnising nativities and deaths with equal lustre, nor omitting ceremonies of bravery in the infamy of his nature.

To the Editors of THE LANCET.

SIRS,—In September last I sent to the meeting of the British Association at Bradford a paper prefaced with the following remarks: "This year being the tercentenary of the publication of Dr. Gilbert's celebrated work 'De Magnete,' in which he announced in the year 1600 that the earth was a magnet, but from which time till now the cause of its magnetism has remained a mystery, the present meeting of the British Association would appear to be a very appropriate occasion for commemorating that event and for suggesting an explanation of the cause which is not at variance with known electrical and meteorological laws, since no reasonable explanation or one that is proof against scientific criticism has yet been offered." My paper arrived late—three days after the British Association had commenced its proceedings, but I was pleased to see that Professor S. P. Thompson lectured at the London Institution at the end of last year on "A Tercentenary of Electricity," and it is with still greater pleasure that I now learn in your columns that the medical profession at Colchester, Gilbert's native place, have combined to erect a marble statue of the famous physician and scientist. I trust a much larger sum will be subscribed than the one mentioned as being actually wanted. I have much pleasure in seconding your appeal and in forwarding to the treasurer my humble contribution.

I am, Sirs, yours faithfully,

Jan. 15th, 1901. FREDERICK GEORGE, M.D. St. And.

THE PROPOSED NEW MUNICIPAL BUILDINGS, ETC., AT BOURNEMOUTH.

To the Editors of THE LANCET.

SIRS,—As a member of the Municipal Buildings Committee of the Bournemouth Town Council, my attention has been called to a communication appearing in THE LANCET of Jan. 12th, p. 116, under the heading of "When is an Improvement not an Improvement," in which the writer has made many inaccurate statements calculated to do this unique health resort considerable harm. I cannot do better than enclose the "statement of facts," which will sufficiently refute such misunderstandings.

As a medical man who has known the town for more than 17 years I shall hail with satisfaction the time when this open space in question is properly drained and laid out as beautiful and healthy pleasure grounds, in place of being a semi-swamp in parts and a possible receptacle for things of an objectionable nature. Instead of putting the ratepayers to an unnecessary expense in refuting misstatements it would be far more to the purpose if these objectors would direct their energies towards strong advocation of more shelters and more seats throughout the town, and the erection of that much-needed pier pavilion, all of which would prove inestimable boons to the invalid visitors to this town and enormously strengthen our hands in the treatment of chest cases and many other forms of disease. The lack of the above is the one crying need of Bournemouth, for it is often a difficulty to encourage patients to go outside their houses to take fresh air unless there is adequate provision for shelter from sudden atmospheric changes. Fortunately, there are signs that we are waking up to this necessity, and medical men can hasten it by making their voices heard in the matter.

I am, Sirs, yours faithfully,

Bournemouth, Jan. 14th, 1901. F. W. CORY.

FENCING AS A THERAPEUTIC MEASURE.

To the Editors of THE LANCET.

SIRS,—I venture to suggest to the profession that the exercise of fencing is not sufficiently used as a remedy in many of the incipient neuroses of adolescence. And my suggestion would involve its adoption more particularly in the case of young girls. As an old student of the foils I am sure that no other pastime open to both sexes can compare with it as a natural diaphoretic, as a training for the brain, the eye, the nervous and muscular systems, and if the proper dress (or undress) be adopted (in girls) the perfect freedom of such costume may be elevated into a future habit which even may discard the "exigencies" (so harmful) of society clothes in their extreme and usual manifestations. In my own practice I have, I am glad to say, never neglected the "prescribing" of the foils, but I am half-sure and half-afraid that it is an omitted recommendation with the profession at large.

I am, Sirs, yours faithfully,

GEORGE H. R. DABBS, M.D. Aberd.

Shanklin, I.W., Jan. 14th 1901.

THE PHARMACEUTICAL SOCIETY AND DOCTORS' SHOPS.

To the Editors of THE LANCET.

SIRS,—We have just seen the article upon "The Employment of Unqualified Dispensers" in THE LANCET of Jan. 5th. There is in the article an error in fact which we think should be pointed out—viz., the writer says: "The Pharmaceutical Society had instigated no less than 46 prosecutions of unqualified druggists' assistants." This is not so. The 46 prosecutions in question were all against doctors' unqualified assistants for selling poison in shops belonging to doctors, and in each case a conviction was secured. We think this correction gives additional weight to the views of the article.—We are, Sirs, yours faithfully,

P. MORISON AND SON,

Solicitors to the Pharmaceutical Society in Scotland.

Edinburgh, Jan. 12th, 1901.

"ISOLATION HOSPITALS."

To the Editors of THE LANCET.

SIRS,—As medical officer to the Hospital for Infectious Diseases at Bishop's Stortford, will you kindly allow me a few lines of explanation regarding the statements which appeared in THE LANCET of Jan. 5th (p. 64), in a letter signed by Mr. Edgar Pittway? I wish to confine myself purely to matters of fact. The two children, W. N—— and A. F——, referred to in Mr. Pittway's letter were discharged from the hospital on Dec. 16th. Both children were quite free from any discharges from either the eyes, ears, or nose, as ascertained by myself. Desquamation in the case of W. N—— was completed. A. F——, at the end of nearly the seventh week had not desquamated at all. M. F——, a sister of A. F——, was admitted to the hospital on Dec. 25th, nine days after her sister had returned home. She was then desquamating freely all over the body. M. N——, a brother of W. N——, was admitted to the hospital on Dec. 27th also desquamating generally. As he was desquamating freely on his hands the process of desquamation was obviously of some standing.

With these facts before me I cannot agree with Mr. Pittway's conclusion that the "return" cases were the cause of the second outbreak of scarlet fever at Henham.

I am, Sirs, yours faithfully,

Bishop's Stortford, Jan. 16th, 1901. E. D. AGNEW.

THE COUNCIL OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

To the Editors of THE LANCET.

SIRS,—It would be most interesting to have an answer to the question—"What is the object of the annual meeting of the Fellows and Members of the Royal College of Surgeons of England?" We are advised by advertisement that a meeting will be held and we are *invited* to attend. Some of us do so at expense and inconvenience to ourselves, when a voluminous report is placed in our hands which we have never seen before, and consequently we have never had any opportunity to acquire the slightest knowledge of its accuracy or contents, whereas the Council have, or should have, a complete mastery of the same and a defence of any weak spots which may be detected at the meeting. This has at last been remedied by the strenuous efforts mainly of the members. Certain proposals are put forward at the meeting and are put to the vote, and as often as not these proposals are carried *nem. con.*, but at the next meeting of the Council our unanimous vote is tabooed and the very opposite is carried by the Council.

Now if I found that any other society, scientific, social, or

commercial, treated my vote in such a manner I should at once withdraw my name as a member and regard the matter as a personal indignity. But in a case where I have given many years of my life in order to get an insight and knowledge of surgery so as to obtain my daily bread I am compelled to put up with the treatment. If I resign my membership I resign that which enables me to gain an honest livelihood. Is this fair? Is it just?

There is one other question I should like to ask. Since a somewhat peculiar circular some time ago was sent out to the Fellows of the College, asking for their opinion as to the advisability of granting some measure of the franchise to the Members, and a certain number of the Fellows voted in the affirmative, I should like to know by whom the names of the recently elected Fellows were selected, and what percentage of the Fellows voted for those names, and also for the recent Act of Parliament which was obtained in order to enable the Council of the College to do that which previously they were unable to do. It is my firm belief that if some of these newly-elected Fellows were fully aware of the fact that not one of the 17,000 Members had any voice or vote in their selection and election they would at once return their diplomas.—I am, Sirs, yours faithfully,

ALBERT S. MORTON, M.D. Durh.

Putney, S.W., Jan. 9th, 1901.

NOTES FROM INDIA.

(FROM OUR SPECIAL CORRESPONDENT.)

Refusal by a Judge of a Medical Certificate and Contempt of Court.—The Appointment to the Victoria Dufferin Hospital in Calcutta.—The Plague Epidemic.

A CURIOUS incident is reported from Colombo. The account which is current is to the effect that Sir W. Bonser, the chief justice, has issued a rule calling on Captain J. B. Reddick, R.A.M.C., to show cause why he should not be committed to prison or otherwise punished for contempt of court. Captain Reddick gave a medical certificate to a Major Pain, who had been summoned to serve on a jury, stating that the major was not well enough to serve. The chief justice, it appears, took exception to the certificate and refused to accept it on the ground that the nature of the illness was not stated on it, and he laid down the dictum that it was for the court to decide whether the statements in the certificate were sufficient to entitle the holder thereof to exemption. The certificate was thereupon rejected. When Captain Reddick discovered this it is reported that he addressed a letter to the chief justice expressing his surprise at the course of action adopted, demanding an apology, and threatening on failure of a sufficient apology being made to represent the chief justice's conduct to the Imperial authorities. On receipt of this letter, it is said, the chief justice ordered the rule *nisi* to issue.

I understand that Miss Margaret M. T. Christie, M.D. Lond., has been selected for the permanent charge of the Victoria Dufferin Hospital in Calcutta. Amongst lady doctors this appears to be a much-coveted appointment and the competition for the post is said to have been very keen. Miss Christie was one of the lady doctors sent out in 1898 for plague duty and she was posted to Calcutta. The outbreak of that year being so mild there was little opportunity of studying plague, but Miss Christie took an active part in pushing the value of inoculation and in association with Mr. Nield Cook, the health officer, she succeeded in performing over 2000 inoculations The city at that time was greatly alarmed about the plague and the authorities had made great preparations against it. Amongst other duties Miss Christie acted as lady superintendent to the staff of European nurses who had been imported into Calcutta in the event of emergencies. Miss Christie will take up her new post in February.

About the plague epidemic there is little to record this week. There are distinct indications of its development once more in Bombay city. In three of the old infected districts—Mandvi, Bhuleshwar, and Byculla—the signs of recrudescence are marked and there are more patients in the hospitals under treatment for plague. The plague mortality in the Behar district of Bengal is very large. Captain A. Gwyther, I.M.S., has been placed there on special duty. It is a good sign that the people are coming forward asking to be inoculated, as except for this, disinfection alone is relied on and is being pushed extensively. It is said that an experienced assistant civil surgeon has been sent as health officer to Patna. In Bangalore there appears to be some friction about the plague regulations and the disease is spreading. There is no definite sign of recrudescence at present in Calcutta, but the general mortality is abnormally high. Sporadic cases still keep cropping up in the villages of the Jullunder district of the Punjab.

Dec. 29th.

BIRMINGHAM.

(FROM OUR OWN CORRESPONDENT.)

Christmas Festivities.

THE return of Christmas brings a renewal of the efforts to make glad the season among all the sick and poor. The various hospitals in the city have vied with each other in promoting the happiness and comfort of the inmates, and in providing entertainments and amusements which tend to take their thoughts away from their maladies for the time being. In the Christmastide which has just gone by the General Hospital was especially prominent in this direction, the internal decorations being tastefully and artistically arranged, and the colours and festoons giving an attractive appearance to the wards and rendering them bright and cheerful-looking. There were entertainments in the form of plays by the resident officers, tableaux and concerts among the sisters and nurses, and, not the least enjoyable, an "at home" by the matron—Miss Jones—which was largely attended and much appreciated. While it is no doubt a successful way of brightening the lives of many of the patients it must not be forgotten that all the preparations and participations in such festivities entail an extra amount of work and longer hours, of time and labour drawn from the more serious duties of everyday routine; the more credit, therefore, is due to those whose sympathy and disinterestedness render them willing and anxious to smooth the lives of those whom accident and disease have thrown into such admirable and comfortable quarters during the season of Christmas-time.

Death of Sir John Jaffray.

On Jan. 4th Sir John Jaffray, the first baronet, passed peaceably away to his rest. At the ripe age of 82 years Sir John Jaffray completed a long and active life, of which a great part was spent in the public service of the town of his adoption. Born at Stirling in 1818, he became a reporter for a newspaper after his education at Glasgow, and in 1844 obtained an appointment upon the *Birmingham Journal*. Here, after an interval in which he displayed rare energy, literary ability, and business capacities, he was taken into partnership at the formation of the *Daily Post*, a position which he held with increasing success and advancement. Of liberal principles and pronounced views on important public and social questions, he was always ready with fearless advocacy to expound his ideas for the guidance of the public opinion of the city and the welfare of those among whom he lived and laboured so earnestly. Generous in relation to medical charities and philanthropic institutions, he built in 1885 the suburban hospital known by the name of its founder, the Jaffray Hospital, where the patients who pass from the General Hospital remain until they are able to be removed or to resume their work. In all matters of medical interest he took a prominent part, more particularly at the General Hospital and the Hospital for Women. Of astute business habits and profound commercial knowledge he acquired distinctions and honours which rarely fall to the lot of those who cut their way through obstacles and difficulties, achieving thus a merited and distinguished position in the community which he so long and so actively adorned.

Periodical Collections for Local Charities.

The complete list of the collections for the past year shows a substantial amount for the various charities of the city. The total reaches the sum of £5262 17*s.* 9*d.* In spite of war funds and numbers of minor drains upon benevolence there will be from this source a gratifying addition to the respective funds of the hospitals in the city.

Medical Appointments.

At a meeting of the board of management of the General Hospital on Jan. 4th two new offices were created and appointments made. It has long been a source of difficulty

in dealing with the large number of medical out-patients, and after consideration it was resolved to appoint two casualty assistant physicians. For these offices there were six candidates, the choice falling upon Dr. J. R. Charles and Dr. S. H. Perry, each of whom had held the post of resident medical officer for a lengthened period.

Jan. 15th.

LIVERPOOL.

(FROM OUR OWN CORRESPONDENT.)

The Lord Mayor's Hospitals Century Fund: the Hospital Sunday Collection.

THE twentieth century has opened auspiciously for the medical charities of Liverpool. The fund which the Lord Mayor has inaugurated for the liquidation of the debts of the hospitals is proceeding most satisfactorily, nearly £9000 having been already subscribed towards that object, the total amount required being £22,000. The collections made on Sunday, Jan. 13th, in the various churches and chapels throughout the city and suburbs on behalf of the Hospital Sunday Fund promise to exceed those of last year by a substantial amount. The returns from the various places of worship which have already been published show, in many instances, marked improvement upon last year's figures. The total amount collected will not be fully known for 10 days or a fortnight.

Arsenical Beer in Liverpool and Crewe.

The quarterly report of the public analyst (Dr. Campbell Brown) submitted at the last meeting of the Liverpool Health Committee, stated that out of 298 samples of beer analysed, 52 were found to constitute offences against the Food and Drugs Act. 25 samples contained a trace of arsenic, 20 samples contained a small quantity, four contained one and a half grains per gallon, two contained three-quarters of a grain per gallon, and one contained half a grain per gallon. A discussion took place at the meeting of the committee regarding the prosecution of offending brewers, but no decision was arrived at. The medical officer of health of Crewe has also examined 21 samples of beer and has found traces of arsenic in 10. There were about 30 cases of beer poisoning, two of which were dangerous cases.

The Victoria Central Hospital, Liscard.

On Jan. 1st the New Victoria Central Hospital, Liscard, was formally opened by Mr. James Wright, the chairman of the Wallasey District Council, in the presence of a large and influential gathering. At the recent bazaar held to raise a fund for furnishing the institution the large sum of £6000 was obtained, thus enabling the committee to clear off all liabilities and furnish the hospital in a complete manner. The institution enters on its career free from debt, which is a rare occurrence nowadays in hospital annals. In regard to the maintenance fund, half the necessary amount of £1200 has already been promised. There is accommodation for 40 beds in the building, which are in the nursing charge of a lady superintendent and eight nurses. The hospital received its first patients on Jan. 7th.

The British Congress on Tuberculosis.

Liverpool will be represented at the British Congress on Tuberculosis, which is to be opened by the Prince of Wales on July 22nd in the Queen's Hall, London, by Dr. Rubert Boyce, the energetic professor of pathology at University College, Liverpool, who will act as one of the secretaries of the pathological (including bacteriology) section.

A Liverpool Centenarian.

Mrs. Sarah Smith, residing in Beaumont-street, is reputed to have been born in 1797, so that she is now in her 104th year. The old lady is reported to be in excellent health, her only trouble being an occasional attack of rheumatism, which does not appear to have affected her health to any degree.

The Demolition of Insanitary Property: Local Government Board Inquiry: A Decreasing Mortality-rate.

Mr. E. P. Burse, one of the Local Government Board inspectors, recently heard evidence at the municipal buildings in favour of, and considered objections to, three applications by the Liverpool Corporation for the issue of provisional orders under Section 303 of the Public Health Act, 1875. The first application was for power to alter the Liverpool Sanitary Amendment Act, 1864, so as to enable the corporation to borrow, with the sanction of the Local Government Board, additional moneys for the purchase and demolition of insanitary houses. The town clerk, in support of the application, stated that at various times the corporation had obtained powers to borrow £200,000 for the demolition of insanitary property and the whole had been expended. Other powers were subsequently acquired to borrow additional sums also amounting to £200,000, nearly all of which had been expended. In a short time there would be a further report from the medical officer of health declaring that other houses were in an insanitary condition and unfit for human habitation, and they wished to take time by the forelock, and to provide the means for carrying out this work of improvement. The number of houses which had already been demolished by the corporation was about 6500. An assurance had been given to the Local Government Board by the corporation in regard to re-housing a certain number of the people displaced by the operations of the committee. 182 houses with recreation grounds were in course of erection by the corporation. They had also acquired sites in various directions for building upon; bringing up the total to 843 new houses; each house will accommodate between four and five people. There had been 1602 fewer deaths in Liverpool during the past six months as compared with the corresponding six months of last year, which showed a steady and continuous improvement. This happy result had, no doubt, been considerably helped by the destruction of insanitary areas, the widening of the streets, and the various improvements effected by the corporation in recent years.

Jan. 15th.

WALES AND WESTERN COUNTIES.

(FROM OUR OWN CORRESPONDENTS.)

Cardiff Infirmary.

AS already reported in THE LANCET[1] there was a most unseemly dispute at the December meeting of the executive committee of the Cardiff Infirmary between the members of the medical board on the one hand and some of the other members, including one medical gentleman, on the other hand. The medical board had recommended the appointment of Dr. Owen L. Rhys to the position of assistant house surgeon, but the recommendation was met with a resolution refusing to accept the recommendation and appointing Mr. D. A. Fitzgerald to the post. This resolution was carried. Mr. Fitzgerald was acting temporarily as superintendent of the Cardiff Fever Hospital when a case of plague was treated in that institution, so that he is not unknown in the town, and the medical board would no doubt have heartily accepted the decision of the majority of the executive committee had it not been for an unfortunate expression of opinion by the mayor to the effect that Mr. Fitzgerald was rejected by the board because he was an Irishman and a Catholic, and he further said that the infirmary suffered in the eyes of the public because of the dominating influence of the medical board. "While the doctors are squabbling," said his worship, "patients are dying." This may be a smart epigram, but, like many epigrams, it does not convey the truth. The injustice of the expression was felt so keenly by Dr. Charles Vachell, the senior physician to the infirmary, that he then and there tendered his resignation, and it seemed not improbable that the entire staff would follow his example. This disaster has happily been averted, and at the January meeting the most influential members of the executive committee expressed their entire confidence in the staff, and the persuasions of General Lee, the chairman, even induced Dr. Vachell to withdraw his resignation. The whole incident cannot but be regretted by all those who have the good of the institution at heart, and though the storm may to a certain extent have cleared the air it is none the less to be deplored.

Memorial to the late Mr. F. W. Lewis.

In the first week of the new year Sir John Williams unveiled a memorial fountain at Llandovery which had been erected in memory of the late Mr. F. Williams Lewis, who practised in the town for many years. Mr. Lewis was a student at the Middlesex Hospital in the "seventies,"

[1] THE LANCET, Dec. 29th, 1900, p. 1928.

and after settling in Wales he was appointed Poor-law medical officer and medical officer of health of Llandovery. The fountain is a granite structure and cost about £600. It is the gift of the Rev. T. Evans and Mrs. Evans, who were close personal friends of Mr. Lewis.

Anti-vaccination Tactics.

The anti-vaccinationists have discovered still another method of delaying the vaccination of children. At the police-court held at Abertillery in December there were down for hearing six cases of neglect to have children vaccinated, but as the representative of the local anti-vaccination society objected to a medical man sitting on the bench Mr. W. E. Williams retired and the cases were adjourned for a month. At the adjourned hearing in January the same objection was taken and a further adjournment was made. The clerk to the magistrates very properly ruled that Mr. Williams was not disqualified from hearing the case. It is reported that there have been granted in Monmouthshire 407 certificates of exemption from vaccination since the passing of the Vaccination Act in 1898.

Notification of Measles.

At the last meeting of the Neath Rural District Council it was decided to delete measles from the list of notifiable diseases in spite of the strong protests of Mr. T. P. Whittington, the medical officer of health, and of Mr. James Elias, a medical member of the council and who is also the medical officer of health of the borough of Neath. The only districts in Glamorganshire in which this disease is now notified are Swansea and Neath borough.

Bequests to Medical Charities.

The late Mr. Richard Lewis of Hereford has bequeathed £300 to the Cardiff Infirmary and £150 to the Porthcawl rest.

Sanitation at Oystermouth.

The Oystermouth District Council, which includes within the area of its administration the popular Welsh health resorts known as the Mumbles and Langland Bay, has never displayed very conspicuous energy in carrying out its duties as a sanitary authority; indeed, upon more than one occasion members of the council have resented what they have been pleased to call the unnecessary interference of the medical officer of health of the county of Glamorgan. It is hoped that the appointment of Mr. A. Lloyd Jones, who holds the Diploma in Public Health of the University of Cambridge, to the vacant post of medical officer of health, is an indication that the council has at last become alive to its responsibilities.

Quack Literature.

The high wages prevailing in the colliery districts of Monmouthshire and of South Wales are being taken advantage of by the vendors of quack medicines. The "stomach pills" and the cough lozenges which are disposed of in large quantities on market days probably do little harm if they do no good. This cannot be said, however, of certain literature which is now being distributed broadcast throughout the most populous parts of the country. The vicious character of the publication may be gathered from the use of such expressions in a column headed "How to be happy though married" as "cures obstinate cases" and "regulator of the monthly courses," in connexion with certain lotions and suppositories the mode of application of which is described in considerable detail. Since every right-minded person is agreed that such broadsheets can only do harm there ought not to be much difficulty in securing their suppression.

Aberystwith Rural District Council.

The election of an inspector of nuisances by the Aberystwith Rural District Council was the occasion of some rather unusual proceedings. There were 40 candidates for the appointment, the salary of which is £105 per annum, and included in the number of applicants were the chairman and the vice-chairman of the council. These two gentlemen having been out-voted returned to their places in the council where one proposed and the other seconded the resolution appointing the successful candidate.

Lunacy in Wales.

Dr. R. S. Stewart, the deputy medical superintendent of the Glamorganshire County Asylum at Bridgend, has recently given some interesting details relating to the prevalence of lunacy in Wales. The Welsh counties having the largest proportionate number of lunatics are Brecknockshire, Radnorshire, Montgomeryshire, and Cardiganshire. In Glamorganshire the rate of lunacy is low and in the several unions of that county the rate per 10,000 of the population is in Neath, 24; Swansea, 22; Merthyr, 21; Cardiff, 20; Bridgend, 18; Cowbridge, 18; and Pontypridd, 10.

Newport and Monmouthshire Hospital.

The Newport and Monmouthshire Hospital has received a donation from an unusual source. It appears that the owner of a licensed house, the lease of which is expiring, offered to pay £2000 to the hospital funds in addition to a ground rent of £50 per annum for the lease of a block of buildings on land belonging to the Newport Corporation on condition that he should be allowed to erect a licensed house upon the land. The licensing magistrates having sanctioned the transfer the amount was formally voted to the hospital at the last meeting of the Newport Council, although some of the members protested and urged that it should be paid over to the borough fund or given to the technical instruction committee.

Pembrokeshire and Haverfordwest Infirmary.

This infirmary, an institution containing 34 beds, has been closed in order that the drainage system may be overhauled and reconstructed. The occurrence of a case of diphtheria among the patients led to an examination of the drains, resulting in the discovery of certain defects.

Jan. 14th.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

Dietaries of the Poor in Edinburgh.

UNDER the auspices of the Scottish Society of Economists Dr. D. Noel Paton delivered a lecture on the evening of Jan. 9th in the Accountants' Hall, Queen-street, Edinburgh, on "Dietaries of the Poor in Edinburgh." Dr. Paton has lately been conducting investigations on somewhat similar lines to those so largely carried on in America with the object of ascertaining the energy-producing power of the food used among the people and also the proper amount of food for the average working man. Dr. Paton at this meeting gave an account of the researches which he had conducted. The conclusion which he arrived at was that the poorer classes of working people in the city of Edinburgh did not receive the food necessary for what had been estimated as the amount of energy which an ordinary labourer should be able to expend on his work. In the daily diet of some of the poorest classes whose wages were irregular it had even been found that the free labourers did not receive so much energy-producing food as did the inmates of asylums, hospitals, and prisons in this country. Oatmeal, that maker of Scots' bones and brains, came far down the list of articles of food in the dietaries which Dr. Paton had investigated. Bread, potatoes, milk, vegetables, and beef preceded it. In concluding his lecture Dr. Paton suggested that a first step towards remedying this state of matters might be taken by distributing simple tables among the people showing the amount of work-producing power which could be got for a pennyworth of the various ordinary articles of diet. Some discussion followed Dr. Paton's paper, after which a cordial vote of thanks was given to the lecturer.

Scottish Natural History Society.

At a meeting of the Scottish Natural History Society held on Jan. 10th Dr. David Hepburn delivered a lecture on "The Skull as a Basis for Race Classification." There were various methods of classifying the human race, such as the colour of the skin, the character of the hair, geographical distribution, &c., and Dr. Hepburn showed that the information derived from careful examination of the skull might be similarly utilised. He described the method of obtaining the measurement of the cranial box and showed how a classification of skulls might be made on the figures so obtained. He also pointed out the differences between the human skull and that of apes in that particular. He described the method of measurement by tapes and callipers and the system of calculating "indices." Subsequently he discussed the signification of the various results derived from skull measurements apart from their value as aids to a system of classification. He showed that at the time of birth a human infant had a distinctly human brain, while in the rest of its body, notably in its joints and bones, it presented striking resemblances to the anthropoid apes. From the fact that the brain was so clearly in advance of the rest

of the body he argued that the growth of the brain was the primary factor determining the growth of the skull. The lecture was illustrated by limelight illustrations from photographs and also by specimens of various types of skulls.

Cremation in Scotland.

The report of the directors of the Scottish Burial Reform and Cremation Society, Limited, for 1900 states that the number of cremations shows a steady increase every year. Every satisfaction continues to be expressed with the arrangements at the crematorium. The progress of the cremation movement is, however, slow in Scotland, only 75 cremations having taken place since the opening of the crematorium. The operation of the Act which was passed in 1900 granting to local authorities in England power to expend public moneys in erecting crematoriums has not yet been extended to Scotland. Various municipal authorities in England propose to exercise the powers thus given them, and at Hull a municipal crematorium has lately been opened. The directors regret that in spite of the express desire of the health authority the bodies of those who died from plague in the recent outbreak in Glasgow were not cremated, it is believed mainly owing to the opposition of the Roman Catholic clergy. The report goes on to urge that, as the wishes of many persons with regard to cremation have been disregarded after death, the forms of request issued by the society be signed in duplicate.

University of Edinburgh: Annual Report.

The annual report of the University of Edinburgh which has just been published shows that the total number of matriculated students for the past year was 2754. This includes 252 women. Of the total number 842 (including 215 women) were enrolled in the faculty of arts, 161 (including three women) in the faculty of science, 40 in the faculty of divinity, 348 in the faculty of law, 1338 (including 13 women) in the faculty of medicine, and 25 (including 21 women) in the faculty of music. Of the students of medicine 592. or 44 per cent., belonged to Scotland; 332, or nearly 25 per cent., were from England and Wales; 111 were from Ireland; 68 were from India; 209, or 15½ per cent., were from the British colonies; and 26 were from foreign countries. The number of women attending extra-academical lectures with a view to graduation in medicine in the University was 92. The following degrees were granted during 1900:—Master of Arts (M.A.), 125 (including 25 women); Doctor of Philosophy (D.Phil.), 1; Bachelor of Science (B.Sc.), 26; Doctor of Science (D.Sc.), 3; Bachelor of Divinity (B.D.), 3; Bachelor of Laws (LL.B.), 7; Bachelor of Medicine and Master in Surgery (M.B., C.M.), 15; Bachelor of Medicine and Bachelor of Surgery (M.B., Ch.B.), 180 (including 18 women); and Doctor of Medicine (M.D.), 53. The General Council of the University now numbers 8883. The schoolmasters' diploma was conferred on 14 candidates. For the first time in the history of the University the honorary degree of Doctor of Laws (LL.D) was conferred on a woman, Miss E. A. Ormerod, F.R.Nat.Soc., F.E.S., of St. Albans. The local examinations were to be discontinued after the examinations in June. 1901. The total annual value of the University Fellowships, scholarships, bursaries, and prizes now amounted to about £17,820. The first ordinance of the University Court which related to the separation of the teaching of forensic medicine and public health had been approved by the Queen in Council and arrangements were being made to bring its provisions into operation at an early date. The re-cataloguing of the University library for which a portion of Sir William Fraser's bequest had been set apart, was now being carried out under supervision by a special staff of eight cataloguers. By the end of November over 106,000 volumes had been catalogued in more than 90,000 entries and 11,000 cross references. This is believed to be about half the contents of the library. A large special fund for the purchase of standard works was a pressing necessity, it being at present almost impossible to purchase expensive volumes in many branches of science which a well-equipped university library ought to possess. The want of funds was also much felt in connexion with the increasingly large number of works and periodicals connected with scientific research. Three vacancies in the professoriate had occurred during the year through the death of Sir Thomas Grainger Stewart, for 24 years professor of medicine and of clinical medicine; the death of Mr. George Frederick Armstrong, M.A., C.E., professor of engineering and the resignation of Professor John Philip Wood, W.S., of the chair of Conveyancing. The chair of Medicine had been filled by the appointment of Dr. John Wyllie, and Mr. John Little Mounsey, W.S., had succeeded Professor Wood. The chair of Engineering had not yet been filled up. Sir John Batty Tuke had been elected as member of Parliament for the universities of Edinburgh and St. Andrews, in room of Sir W. O. Priestley, whose death had occurred in April. The construction of "The John Usher Institute of Public Health," for which the University was indebted to the munificence of Sir John Usher of Norton, Bart., had during the year made considerable progress. In connexion with the war in South Africa the University had accepted the invitation of the Secretary of State for War to nominate candidates for commissions in various branches of the military service. The Senatus had granted special privileges to students who volunteered for active service and proposed to erect a memorial tablet in the M'Ewan Hall to those who fell in the war. Professor John Chiene had been given leave of absence to enable him to proceed to South Africa as consulting surgeon to Her Majesty's forces and a number of graduates and undergraduates of the University had been on the staff of the Edinburgh and East of Scotland Hospital which had been stationed at Norval's Pont.

Glasgow Royal Infirmary.

The decision of the committee concerned with the rebuilding of the infirmary in reference to the selection of a plan not advised by the assessor continues to excite some comment in the city, but the affair must now be regarded as a *chose jugée*. At a meeting held on Jan. 11th a report from the newly-appointed architect regarding the order and method of reconstruction was received and adopted. This involves the postponement of the re-erection of the front of the infirmary in the form of a Jubilee memorial until after the main part of the new hospital has been built, a decision demanded by the necessity for providing accommodation for patients, though certainly to be regretted on sentimental grounds. Concerning the financial aspect of the new undertaking it was stated that the committee had already nearly £100,000, and that with this they proposed to proceed with the erection of the north or surgical block. This it is calculated will occupy fully two years, after which a further appeal for funds will be necessary. Before the entire scheme is completed it is calculated that some eight or 10 years will have elapsed, and thus the claim upon the charitable public will assume a less severe front than if an attempt were made to raise the entire £240,000 at one time.

Glasgow Samaritan Hospital.

It has been decided by the medical staff, with the approval of the directors, to further develop the clinical teaching opportunities of the hospital by the institution of courses of lectures on gynæcology. The first course is to be given by Mr. J. Stuart Nairne, F.R.C.S. Edin., and is to commence on Jan. 23rd. The lectures are open to all medical practitioners.

Glasgow Sewage Disposal.

The town council of Glasgow, with a view to cultivate public interest in municipal undertakings, has instituted a course of popular lectures on the work of the several corporation departments and the fifth lecture of the series was delivered on Jan. 13th by Mr. A. B. M'Donald, city engineer. The subject dealt with was the disposal of the city sewage. Amongst other interesting items it was stated that there are at present 297 miles of subterranean sewers in the city, the greater part of which discharge into the harbour. The volume of sewage amounts to 55,000,000 gallons each day and it is calculated that each million gallons contribute 40 tons of pollution to the river. The sewage works constructed six years ago at Dalmarnock deal with some 16,000,000 gallons of sewage daily and in this proportion diminish the objectionable matter introduced into the Clyde, which still, however, receives daily some 1560 tons of sewage sludge. It has now been decided by the construction of 30 miles of river sewers to intercept the whole drainage which at present enters the river and to carry it beyond the city boundary where it is to be purified by the precipitation and filtration method now in operation at Dalmarnock. The works designed to effect this will, with the sole exception of the London main drainage area, be the largest in the world, and will serve an area of 29 square miles, which is to include not only Glasgow but a number of neighbouring towns. The

volumes to be dealt with, including rainfall, are estimated at 160,000,000 gallons daily.

Glasgow University.

The memorial window to the late Principal Caird which has been placed in the Bute Hall was unveiled on Jan. 12th in the presence of a large company. Among those taking part in the ceremony were Principal Story, the Master of Baliol (Dr. Edward Caird), Sir William T. Gairdner, K.C.B., and Mr. James A. Campbell, M.P. The scheme for the extension and better equipment of the University is about to take definite shape and the public will shortly have an opportunity of sending in their subscriptions. It is announced that a sum of £21 000 has already been promised. The executive committee has been appointed and includes the names of Professor J. G. McKendrick, Professor J. Glaister, and Professor R. Stockman as representatives of the medical faculty. On the motion of Dr. D. C. McVail the University Court has approved of the principle of the institution of a summer session in the faculty of arts and has requested the Senate to consider and advise on the question.—Professor De Burgh Birch, of the Yorkshire College, Leeds, has been appointed an examiner in physiology and Dr. James Ritchie, of Oxford University, an examiner in pathology. The Gifford lectures on Natural Religion during the present session are being delivered by Dr. Edward Caird, formerly professor of moral philosophy in the University.

Jan. 14th.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Noxious Gases in Dwelling-houses.

THE simultaneous deaths of two persons well known in the fashionable world of Paris from some cause which remains as yet undiscovered (I will say at once that either suicide or homicide is out of the question) has turned the attention of hygienists to the escape of toxic gases either from a stove in the house itself or in that of a neighbour. Cases of asphyxiation by carbonic oxide, which were very common when slow-combustion stoves of the Choubersky type were so much in use, have of late become less frequent since this kind of stove has been less in use. But they probably throw a light on the decease of certain persons found dead and cold in bed whose deaths might easily be put down to a ruptured aneurysm or some such cause but which medical men too often recognised as due to carbonic oxide coming from a stove in the room or, more treacherously still, through faults in the chimney of a neighbour's house who used this method of warming. It is true that the experts have not so far irrefutably demonstrated that the deaths of Monsieur and Madame T—— were due to carbonic oxide poisoning, and experiments are still being made with animals placed in the room with the suspected stove alight. But owing to the position of the victims widespread excitement has been aroused, and the fatality has done more to cause the subject to be threshed out than all the reports of engineers for 20 years. As a matter of fact I may say that a scandal of any kind does more to bring about administrative or moral improvement than anything else. The Prefect of Police has accordingly just nominated a committee composed of engineers, hygienists, and architects whose duties are altogether novel. If any tenant complains of noxious smells from the chimney and the landlord maintains that these are quite usual, that everything is in perfect order, and that no alteration is necessary, the committee will examine into the tenant's case, and if they find his complaint justified the landlord will have to carry out the necessary repairs. If he refuses the committee will order the work to be done and will charge the expense to the landlord.

The Association of Medical Men of the Seine and Hospital Reform.

The last meeting of the Association of Medical Men of the Seine was extremely interesting and some very important decisions were arrived at. After an admirable paper by M. Jamin, the President, entitled "Optima Medicorum Concordia," had been read, M. Philippeau, the treasurer, read his report, which, among other things, showed that the association had a balance in hand of 10,000 francs. The association then elected 125 new members and also nominated its council for 1901. The yearly subscription was reduced from 15 to 10 francs, and it was agreed that fresh blood should be introduced into the council, only members of the managing committee being eligible for re-election. The sitting then became very animated over the discussion on the report of M. Thiery on hospital abuse and gratuitous medical advice, and in reference to these questions M. Dorison presented the demands of the medical men attached to the Bureaux de Bienfaisance. These were as follows. The Medical Society of the Bureaux de Bienfaisance, considering that the system of out-patient hospital relief (1) does not practise a proper sorting out of the persons who apply for relief so that only the poor, who alone have the right to gratuitous advice and medicine, are selected; (2) is not now justified as formerly by the presence of the senior medical officers; and (3) is simply since the creation of the dispensaries a replica (*double emploi*) of the work carried on by the Bureaux de Bienfaisance, except that it does not supply medicine (a fact which is equivalent to saying that the hospital out-patient system only provides for persons who can pay for their medicine and therefore for those very people for whom gratuitous advice was not provided)—the association, taking all this into consideration, resolves: (*a*) that the out-patient departments of hospitals should be done away with; and (*b*) that admission orders for the hospitals should only be provided by the medical officers of the Bureaux de Bienfaisance, except of course in cases of urgency as laid down in the regulations. M. Dorison was unable to be present and so could not defend the views brought forward by him or reply to questions, while the members of the association not having all the facts before them could not discuss the matter with full knowledge. These questions of charitable relief are difficult for anyone who has not studied them carefully and much more so when they are suddenly sprung upon an audience. Some of the members present had but the scantiest knowledge of the questions at issue; others went off into the discussion of parallel questions such as the right of the Assistance Publique to sell or buy sites, sanatoria, &c., all questions excellent in themselves but beside the mark on this occasion. Finally, however, the meeting, asked for its opinion upon the report of M. Dorison, unanimously passed the following motion:—

The Association of Medical Men of the Seine hereby resolves that the out-patient department of the hospitals should be done away with.

The question of admission to the hospitals, which was somewhat more delicate, gave rise to a long debate. Finally, the following motion, standing in the names of M. Mabec and M. Le Baron, was carried:—

The Association of Medical Men of the Seine assembled in general meeting resolves, that hospital treatment should be reserved solely for the poor and needy, and should be absolutely gratuitous.

A special committee was appointed to consider ways and means for bringing about this result.

Total Gastrectomy; Recovery.

At a meeting of the Academy of Medicine held on Jan. 8th, M. Boeckel read a paper upon the case of a woman, aged 38 years, upon whom he had performed total gastrectomy some months ago for a malignant growth supervening upon an old ulcer. This is the first operation of the kind which has been performed in France, and M. Boeckel remarked that the operation was not only compatible with life, but it brought about a great improvement in the condition of the patient. If the new growth were well defined and the neighbouring organs were healthy the operation might well be successful. Whether absolutely so M. Boeckel could not at present say, but that it would be successful for a certain time the three cases which had been reported in other countries and that by M. Boeckel himself showed without doubt. After the opening of the abdomen the operation was divided into five stages, as follows: (1) the freeing of the greater curvature by division of the gastro-colic ligament; (2) the freeing of the upper pole of the stomach by dividing the cardiac end when clamped between two pairs of forceps; (3) the freeing of the lesser curvature by division of the gastro-hepatic ligament; (4) the freeing of the lower pole of the stomach by dividing the first part of the duodenum clamped in the same way as the cardiac end; (5) the union of the cardiac end with the duodenum. Stitching the abdominal wall, no drainage being employed, finished the operation. M. Boeckel's patient made an uninterrupted recovery. The wound united by first intention, no fistula resulted, and the patient got up on the twenty-second day and left the hospital on the thirty-third day. The

digestive functions were soon re-established and were satisfactorily performed so long as the patient was fed with small quantities of easily digested food at frequent intervals. As showing that assimilation was properly carried on he would mention that the patient gained 20 pounds in weight.

Jan. 16th.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

The Case of Professor Neisser.

THE incident in which Professor Neisser figured prominently, as mentioned in THE LANCET of March 31st, 1900, p. 970, seems now to be closed. It will be remembered that he was censured both in Parliament and in the daily newspapers for having, as his detractors alleged, performed inoculations of syphilitic virus on patients in his clinic; the actual facts, however, were of a much less culpable nature, for the experiments in question were in reality injections of the sterilised blood serum of syphilitic persons given to prostitutes and to two children in the hope of producing immunity. In the Parliamentary debate which took place some months ago the Minister of Public Instruction stated that the experiments had not been lightly undertaken but had been prompted by an eminently humane motive. Professor Neisser had, however, made the injections without the consent of the patients, and a prosecution was therefore resolved on, but as the alleged offence had been committed six years ago proceedings could not be taken in an ordinary court of law. Another way was accordingly found. Professor Neisser holds an appointment at a State university, and being therefore an official responsible to the Government the Government prosecuted him before a court of discipline. Several patients and some of the students and members of the medical staff of the clinic who had assisted at the experiments were summoned as witnesses, but owing to the long period which had elapsed since the occurrences in question much time was consumed before the addresses of all the witnesses could be ascertained, so that the decision of the court was given only a few days ago—namely, more than eight months after the debate in Parliament. The proceedings before a court of discipline are never public, so that no particulars can be given except that the accused was declared guilty of conduct unbecoming his position as a professor at a State university; he has not been removed from his appointment as professor, but he has been ordered to pay a fine and has been severely reprimanded. It is to be hoped that the matter is now at an end and that public feeling, which was at one time greatly excited by the misrepresentations that were current, will now be appeased. The Minister of Public Instruction has also addressed a circular to the principal officers of clinics, whether in connexion with universities or not, drawing their attention to the case of Professor Neisser, advising them to abstain from experiments which are not directly concerned with the cure of disease or the production of immunity, and stating that the law does not allow any dangerous treatment or operation to be undertaken without the patient's consent. He also makes the principal officers responsible for any misdemeanour in this respect that may be committed by their assistants or other members of the staff.

An Unauthorised Necropsy.

Another alleged medical scandal has been reported lately by the Berlin daily newspapers. Dr. Hebold, the chief medical officer of the Berlin Municipal Asylum for Epileptics at Wuhlgarten, is said to have made a post-mortem examination of an inmate of the asylum although the parents of the deceased had expressly declined to allow the body to be opened. The deceased was described as being one of the worst cases in the asylum, having sometimes as many as 50 fits in a day. Dr. Hebold removed the brain immediately after death and ordered a wreath to be put on the head to conceal the traces of the necropsy. But his most blameable action was that he exhumed the body on the night after the funeral and removed the head, which was afterwards preserved in alcohol. These facts were disclosed by an attendant who had been dismissed by Dr. Hebold and who in this way revenged himself upon his former master. Dr. Hebold, together with two attendants at the asylum who had assisted him, will be prosecuted, and the municipal council will perhaps be forced by public opinion to dismiss him from his office. Apparently Dr. Hebold has been misled by his scientific zeal to commit a grave misdemeanour repugnant to the majority of the medical profession.

Plica Polonica.

A collective investigation on the frequency of plica polonica in the eastern districts of Prussia has been made by the medical department. The localities which formed the subject of inquiry were the districts of Posen, Bromberg, and Marienwerder, where the greater part of the population are Poles. It was stated that people suffering from plica polonica were found in 385 towns and villages of the district of Marienwerder, in 582 of Bromberg, and in 820 of Posen. The number of patients was 1372, 1858, and 2507 respectively, of whom 682 were males and 5055 were females. The great majority were Poles. It is very difficult to eradicate this repulsive disease because the general ignorance of the population is a serious impediment to the adoption of hygienic measures. Moreover, some of these people are of opinion that plica polonica is a kind of prophylactic against certain diseases and that it would be dangerous to clean the hair in these cases.

Disinfection of Sponges.

A new method for the disinfection of sponges has been described by Dr. Elsberg of New York in the *Centralblatt für Chirurgie*. He maintains the impossibility of disinfecting sponges by boiling or by steam, as is done in the case of other surgical materials, and proposes the following method. The sponges are put for 24 hours in an 8 per cent. solution of hydrochloric acid to clear them from calcareous matter and dirt and are then washed in water. They are afterwards boiled for from five to 20 minutes in a solution of 10 parts of potash and 20 parts of tannic acid in 1000 parts of water and washed again in sterilised water or in a solution of carbolic acid till the brown colour of the tannate of potash has disappeared. They are finally preserved in a solution containing from 2 to 5 per cent. of carbolic acid. By this treatment the sponges do not lose any of their good qualities; they remain porous, elastic, and soft, even although they may have been boiled several times. By bacteriological examination it was found that large sponges infected with streptococci and the bacillus of anthrax and its spores proved to be absolutely sterile after five minutes' boiling in the above solution. Dr. Elsberg therefore recommends a return to the use of sponges which have of late almost disappeared from operating-rooms owing to the fear of their conveying infection.

Jan. 14th.

Obituary.

ARCHIBALD HAMILTON JACOB, M.D. T.C.D., F.R.C.S. IREL.

DR. ARCHIBALD HAMILTON JACOB died on Jan. 12th at his residence, Ely-place, Dublin, from an attack of bronchial asthma, from which disease he had been a sufferer for some years. By his death at 63 years of age his medical friends and colleagues in Dublin and the medical profession all over Ireland have lost a surgeon and colleague whose place it will be very difficult to fill. Dr. Jacob obtained the M.D. of Trinity College, Dublin, in 1862, and has been a prominent Fellow of the Royal College of Surgeons in Ireland for 37 years. He filled the position of professor of ophthalmology in that College for many years, was a senior of its Council and in 1882 was unanimously elected its secretary. In 1866 he succeeded his eminent father as ophthalmic surgeon to the City of Dublin Hospital and in 1872 he opened the Dublin Ear and Eye Infirmary, acting as its chief surgeon, while he subsequently filled the office of ophthalmic surgeon to the House of Industry Hospitals. For some years, while chief surgeon to the Dublin Eye and Ear Infirmary he was also ophthalmic surgeon to the Richmond, Whitworth, and Hardwicke Hospitals and to the City of Dublin Hospital as well.

In 1880 he had the honour of being appointed oculist in ordinary to his Excellency the Lord Lieutenant of Ireland—Earl Cowper—a position which he has filled under all succeeding Viceroys to the present time. There was no position of honour in Dublin medicine to which Dr. Jacob could

not have attained, but he always preferred largely to devote his talents and his unselfish energies to the advancement of his profession in public paths. He served as President of the Irish Medical Association, and during his term of office and ever since he devoted much of his time to the interests of his poorer brethren of the medical profession and to the advancement of their just claims. He was chief editor and proprietor of the *Medical Press and Circular*, and for many years he proved a fearless and able advocate of the rights of the Poor-law medical practitioners of Ireland to an adequate salary, independence, and pension in old age. He inherited the ability and public spirit of his father, and in advocating a cause by eloquent speech and pen never stayed to think whether he was serving his own personal interest and his own professional welfare. Those for whom he did so much cannot soon forget him, and his memory will long be held in high repute in medical and private circles in Dublin, not only for his eminent ability but for his fearless, upright, and kindly character. The Council and Fellows of the Royal College of Surgeons in Ireland attended his funeral on Wednesday, Jan. 16th, when his remains were removed from the house where he and his father lived for so many years at Ely-place.

EUGENE GODDARD, M.D. DURH.

A WIDE circle of friends and patients will be grieved to hear of the death of Dr. Eugene Goddard of Highbury New Park, N. After a morning's hard work he was seized with a rigor followed by faintness, frequent vomiting, and indications of abdominal mischief which ultimately developed into general peritonitis resulting in death on Jan. 13th, the seventh day of his illness. Those who had the pleasure and advantage of Dr. Goddard's acquaintance will severely feel their loss. To a mind generally well stocked were added remarkable clearness and fluency of language and a fund of humour which never failed to give point to his words. Thorough in all he undertook, prompt and decided in action, scrupulously upright and fearless, he was always a courteous gentleman. He seemed to impart brightness to all around him and most of all to those who sought his professional aid, and great was the confidence which his patients placed in him and the esteem with which they regarded him. Dr. Goddard recognised the gravity of his illness and met his death at the comparatively early age of 60 years with cheerful resignation and courage.

DEATHS OF EMINENT FOREIGN MEDICAL MEN.—The deaths of the following eminent foreign medical men are announced:—Dr. Ephraim Ingals, formerly Professor of Materia Medica and of Forensic Medicine in the Rush Medical College, Chicago.—Dr. Dubrueil, a well-known Montpellier surgeon.—Dr. Duclos of Tours, Corresponding Member of the Paris Academy of Medicine.

Medical News.

EXETER WATER SCHEME.—It is estimated that the new water scheme for Exeter will cost about £48,000.

IN MEMORIAM.—For the endowment of a bed, in memoriam, the treasurer of Guy's Hospital has received £1000 from "G. R."

APPOINTMENT OF A MEDICAL OFFICER OF HEALTH.—At the meeting of the Rhondda District Council held on Jan. 11th Dr. D. J. Jenkins, assistant medical officer of health for Bethnal-green, was appointed medical officer of health for the Rhondda district. There were 29 candidates.

HEALTH OF BRISTOL.—At the meeting of the Bristol Health Committee held on Jan. 8th Dr. D. S. Davies, the medical officer of health, reported that 8972 births were registered during 1900, giving a birth-rate of 27·8 per 1000, compared with 29 per 1000 for 1899. This is the lowest birth-rate which Dr. Davies has recorded in Bristol. The number of deaths was 5397, equal to a rate of 16·6 per 1000, as against 18·2 per 1000 for 1899. The infantile mortality under one year per 1000 births was 182, which is the lowest recorded for the past ten years. The deaths registered from the principal zymotic diseases were equivalent to a rate of 1·8 per 1000, the same as recorded in the previous year.

LUNACY IN GLOUCESTERSHIRE.—At the meeting of the Gloucestershire County Council held on Jan. 7th it was reported that 243 patients had been admitted to the Gloucestershire County Lunatic Asylum in 1900, against 292 in 1899; the average number resident in the asylums were 1054, against 1066 in the preceding year. Profit to the amount of £2651. which had accrued from private and other patients, had been applied to the reduction of the county rate. The charge for patients was now 9*s*. per week.

PLYMOUTH ROYAL EYE INFIRMARY.—The annual meeting of the supporters of this institution was held on Jan. 9th, under the presidency of Mr. H. Serpell. The report stated that 2289 patients had been treated during 1900, including 249 in-patients. 1980 patients were treated in 1899. The financial statement showed that the income was satisfactory and that the expenditure amounted to £1073, against £813 in the previous year. The cost of the new buildings amounted to £16,569. The committee acknowledged £1000 from Sir Massey Lopes towards the endowment fund and mentioned that a similar amount was given by him in 1899. As the necessary expenditure in carrying out the work of the new infirmary will be great the committee appeal for increased subscriptions.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.—A quarterly court of the directors of this society was held on Jan. 9th, at 11, Chandos-street, W., the President, Mr. Christopher Heath, being in the chair. 16 new members were elected, and the deaths of Dr. Potter, acting treasurer, and Dr. Stewart were reported. Mr. Christopher Heath proposed from the chair, seconded by Dr. C. J. Cullingworth, as follows:—

> The quarterly court of directors of the Society for Relief of Widows and Orphans of Medical Men desires to record its great regret at the recent death of Dr. Potter, acting treasurer, a most energetic officer of the society, and also desires to express to Mrs. Potter its deep sympathy with her and her family in their bereavement.

Fresh applications for relief were read from two widows and grants at the rate of £50 per annum were made to them. It was resolved that a sum of £1229 10*s*. be distributed among the 49 widows, 12 orphans, and six recipients from the Copeland Funds now in receipt of grants. The Christmas present, amounting to £531, had been given on Dec. 17th. The expenses of the quarter were £78 9*s*.

ROYAL METEOROLOGICAL SOCIETY.—The annual general meeting of this society was held on Dec. 16th at the house of the Institution of Civil Engineers, Great George-street, Westminster. Dr. C Theodore Williams delivered the presidential address, taking for his subject "The Climate of Norway and its Factors." He considered that the meteorology of Norway should prove an attractive study for the society as having much in common with that of our country, both the Norwegian and the British shores being influenced by the same Gulf Stream and having their winters and summers tempered by the same equalising agency. The factors which influenced the climate were (1) the insular character of the country; (2) the distribution of the mountain ranges, which explained to a large extent the rainfall; (3) the waters of the ocean, which from a variety of circumstances came into close connexion with much of the country and thus tempered extremes of climate; and (4) the sun, which in that latitude remained in the summer long above the horizon and in the winter long below it. The address was illustrated by a large number of lantern slides of Norwegian scenery, embracing mountains, glaciers, floods, &c.

THE ROYAL COMMISSION ON SEWAGE DISPOSAL.—Sir Michael Foster, M.P., F.R.S., Major-General Phipps Carey, Colonel Harding, and Mr. J. J. Willis, the visiting members of the Commission, recently visited the Reigate Corporation sewage works at Redhill to inspect the Candy-Caink Revolving Sprinkler System and Polarite Oxidation Bacterial Bed which have been in operation there for over two years. They were met at Redhill by the mayor, the borough engineer (Mr. W. H. Prescott), Mr. Frank Candy, and Mr. F. Pullen Candy, and they made a careful investigation of the system. It is claimed for this system that by means of the

polarite oxidising aerobic bed, fed in an intermittent continuous manner by the Candy-Caink Revolving Sprinklers, with about half an hour's treatment a very strong sewage containing tannery and brewery refuse can be converted into a bright, odourless, and oxygenated effluent. After the inspection the members of the Royal Commission adjourned to the Town Hall to take the evidence of Mr. Frank Candy, General Manager of the International Purification Syndicate, and of the borough engineer, Mr. Prescott, who explained the working of the system and tendered analytical results showing an average purification of 97 per cent.

PRESENTATIONS TO MEDICAL MEN.—A large number of the residents of Llandovery assembled on Jan. 3rd in the principal public thoroughfare of the town to witness the unveiling of a massive granite fountain erected to the memory of the late Mr. Frederick W. Lewis, M.B. Lond., of Stoke Newington-road, by his devoted friends, the Rev. Thomas Evans, J.P., and Mrs. Evans, formerly of Henllys, at a cost of £500.—On Jan. 1st Mr. John Moorhead, M.D.R.U.I., M.R.C.S. Eng., of Weymouth, on his retirement and in recognition and appreciation of his 43 years' valuable services to the Weymouth Royal Hospital, was presented by the Mayor of the borough on behalf of the subscribers with a silver epergne and candelabrum, accompanied by an album containing an artistically illuminated address. Dr. Moorhead was the first honorary medical officer to the institution.—Mr. Hunter U. Walker, L.R.C.P., L.R.C.S. Edin., and Mrs. Hunter Walker of Clapton, have been the recipients of a silver inkstand and pens from the ladies of the Clapton Presbyterian Church in acknowledgment of their services in conducting a course of ambulance lectures connected with the St. John Ambulance Association. All the members of the class obtained the Red Cross certificates.

Appointments.

Successful applicants for Vacancies, Secretaries of Public Institutions, and others possessing information suitable for this column, are invited to forward it to THE LANCET Office, directed to the Sub-Editor, not later than 9 o'clock on the Thursday morning of each week, for publication in the next number.

ALEXANDER, JOHN DAVEY, L.R.C.P. Ed., L.F.P.S. Glasg., has been re-appointed Medical Officer of Health for the Porthcawl (Glamorganshire) Urban District.

BAILEY, BERNARD E. G., M.R.C.S., L.R.C.P., has been appointed House Physician to the East London Hospital for Children and Dispensary for Women, Shadwell, E., vice Oswin Shields.

BEESLEY, CLARENCE, L.R.C.P., L.R.C.S., D.P.H. Cantab., has been appointed Medical Officer of Health to the Budleigh Salterton Urban District, vice A. W. Kempe, resigned.

CONSTANT, FREDERICK, L.D.S. Eng., has been appointed Honorary Dental Surgeon to the Gravesend Hospital.

CULLEN, J. J., L.R.C.P., L.R.C.S. Irel., has been re-appointed Medical Officer, Castleknock and Blanchardstown District, county Dublin.

DICKENSON, G. O. M., M.B., B.S. Durham, has been appointed Assistant Medical Officer, Northumberland County Asylum, Morpeth.

EDWARDS, W. LLOYD, L.R.C.P. Lond., M.R.C.S., has been appointed to the Medical Charge of the troops at Barry Island, South Wales.

FORREST, J. G. S., L.R.C.P. Lond., M.R.C.S., has been appointed Medical Officer for the Workhouse, Thingoe Union, vice C. E. Priestley, resigned.

INGLE, CHARLES DURBAN, L.R.C.P. Lond., M.R.C.S., has been appointed Medical Officer for the No. 2A district of the Langport (Somerset) Union.

JONES, M. P., L.R.C.P. Lond., F.R.C.S. Eng., has been appointed Honorary Consulting Physician to the Royal Infirmary, Alfreton.

LISTER, THOMAS DAVID, M.D. Lond., M.R.C.P. Lond., has been appointed Assistant Physician to the Royal Hospital for Children and Women, Waterloo-road, London.

MACNAMARA, J. P., L.R.C.P. Lond., L.R.C.S. Irel., has been appointed Medical Officer of the Ladywell Workhouse, St. Olave's Union.

MARTIN, JOHN MIDDLETON, B.A., M.B., B.Ch., D.P.H. Cantab., L.S.A., has been appointed Medical Officer of Health for the Nailsworth Urban District Council (Gloucestershire), vice Thomas Partridge, resigned.

NIALL, EUGENE M., M.B. Lond., has been appointed House Surgeon to the West London Hospital, Hammersmith-road.

PENNY, FRANCIS, M.R.C.S., L.S.A., has been appointed a Medical Officer with the troops in South Africa.

PERCIVAL, BEAUMONT, M.B. Cantab., M.R.C.S., has been appointed House Surgeon to the Northampton General Infirmary.

RIGBY, HUGH MALLINSON, M.B., B.S. Lond., F.R.C.S. Eng., has been appointed Surgeon to the Poplar Hospital for Accidents, London.

ROSS, H., M.B., C.M., Aberd., has been appointed Medical Officer, Stratford-on-Avon Hospital.

SARGENT, P. W. G., M.B., B.C. Cantab., L.R.C.P. Lond., M.R.C.S., has been appointed Surgical Registrar, St. Thomas's Hospital, London.

SHIACH, SAMUEL ALLEN, M.D., C.M. Edin., has been appointed Medical Officer and Public Vaccinator for the St. Mellons District by the Newport (Mon.) Board of Guardians.

SPARKS, C. E., M.B., B.C. Cantab., has been appointed, *pro tem*, Medical Officer for Hersham District, Chertsey Union.

STEUART, M. BABINGTON, M.B., C.M. Edin., has been appointed District Medical Officer for Bovey Tracey and Ilsington (North Devon). Corrected notice.

TURNER, T. W., L.R.C.P. Lond., M.R.C.S., has been appointed District Medical Officer, Woodstock Union, vice H. Saunders.

WALKER, HUNTER URQUHART, L.R.C.P., L.R.C.S. Edin., has been appointed by the Home Secretary Divisional Surgeon of the Police for Hackney, N.E.

WARBURTON, W. P., L.R.C.P., L.R.C.S. Edin., L.F.P.S. Glasg., has been appointed Workhouse and District Medical Officer, Skirlaugh Union, vice C. Soloman, resigned.

Vacancies.

For further information regarding each vacancy reference should be made to the advertisement (see Index).

BIRKENHEAD BOROUGH HOSPITAL.—Honorary Dentist.

BIRMINGHAM WORKHOUSE INFIRMARY.—Assistant Resident Medical Officer. Salary £100 per annum, with furnished apartments, rations (which do not include alcoholic liquors), coals, gas, laundry, and attendance.

BOLTON INFIRMARY AND DISPENSARY.—Senior House Surgeon. Salary £120 per annum, with furnished apartments, board, and attendance.

BOROUGH OF RICHMOND (SURREY).—Medical Officer of Health. Salary £450 per annum, and will be recommended for appointment as Visiting Medical Officer to the Borough of Richmond (Surrey) and Heston and Isleworth Urban District Joint Isolation Hospital at an additional salary of £50 per annum.

BRADFORD ROYAL INFIRMARY.—Dispensary Surgeon. Salary £100 per annum, with board and residence.

BRIDGNORTH AND SOUTH SHROPSHIRE INFIRMARY, Bridgnorth.—House Surgeon. Salary £80, with board and lodgings in the infirmary.

BRISTOL CITY HOSPITALS.—Resident Medical Officer at the Ham Green Fever Hospital. Salary £150 per annum, with board, lodging, and washing.

CHELSEA HOSPITAL FOR WOMEN, Fulham-road, S.W.—Clinical Assistant, tenable for three months on payment of £8 8s.

CHORLTON-UPON-MEDLOCK DISPENSARY, Manchester.—Resident House Surgeon, unmarried. Salary £120 a year, with furnished rooms and attendance.

COUNTY ASYLUM, Shrewsbury.—Junior Assistant Medical Officer. Salary £130 per annum, rising by £10 a year to £150, with board, lodging, and washing.

DARLINGTON HOSPITAL AND DISPENSARY.—House Surgeon, unmarried. Salary £100 per annum, with board and lodging, and an allowance for cab hire.

DENTAL HOSPITAL OF LONDON AND LONDON SCHOOL OF DENTAL SURGERY, Leicester-square, W.C.—Demonstrator to superintend the teaching and work of the new students, &c. Honorarium £200 per annum. Also two Demonstrators to assist the Senior Students, one at an honorarium of £100 per annum, and one at an honorarium of £80 per annum.

DONCASTER GENERAL INFIRMARY AND DISPENSARY.—Assistant House Surgeon, unmarried. Board and residence provided.

EVELINA HOSPITAL FOR SICK CHILDREN, Southwark-bridge-road, London.—Senior Resident Medical Officer. Salary £70, with board and washing. Also Pathologist. Salary 100 guineas per annum.

FISHERTON HOUSE ASYLUM, Salisbury.—Assistant Medical Officer, unmarried. Salary £150 per annum, with board, lodging, and washing.

GENERAL HOSPITAL, Nottingham.—House Physician for two years. Salary £100, rising £10 a year to £120, with board, lodging, and washing.

GUILDFORD UNION.—District Medical Officer and Public Vaccinator, Woking District. Salary £80 per annum and vaccination fees.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, Bloomsbury, W.C.—House Surgeon. Salary £20, with board and residence in the hospital.

HOSPITAL FOR WOMEN, Soho-square, London, W.—Assistant Physician, also Assistant Surgeon.

LEICESTER INFIRMARY.—Second Assistant House Surgeon. Salary £80 per annum, with board, apartments, and washing.

LINCOLN HOSPITAL FOR INSANE.—Locum Tenens for six weeks from about 6th of February. Three guineas a week.

LIVERPOOL STANLEY HOSPITAL.—Junior House Surgeon. Salary £70 per annum. Also Third House Surgeon as Ambulance Surgeon. Salary £70 per annum, with board, residence, and washing.

LONDON LOCK HOSPITAL.—House Surgeon to the Female Hospital. Salary £80 per annum, with board, lodging, and washing.

MILLER HOSPITAL and ROYAL KENT DISPENSARY, Greenwich-road, S.E.—Junior Resident Medical Officer, tenable for six months, with prospect of re-election as Senior. Salary at the rate of £60 per annum, with board, attendance, and washing.

MONKWEARMOUTH AND SOUTHWICK HOSPITAL, Sunderland.—House Surgeon, unmarried. Salary £100 per annum, with board, residence, and washing.

NOTTINGHAM GENERAL DISPENSARY.—Assistant Resident Surgeon. Salary £140 per annum, all found except board.

OLDHAM INFIRMARY.—Senior House Surgeon. Salary £100 per annum, with board, residence, and washing.

PARISH OF ST. GILES, CAMBERWELL.—Assistant Medical Officer, twenty-one to thirty years of age, for the Workhouse at Gordon-road, Peckham. Salary £120 per annum, with furnished apartments outside the Workhouse, and an allowance of £1 1s. weekly in lieu of board and washing.

QUEEN ADELAIDE'S DISPENSARY, Bethnal-green, E.—Resident Medical Officer, unmarried, and under 35 years of age. Salary £100 per annum, with furnished apartments, coal, gas, and attendance.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.—Assistant Resident Medical Officer for four months. Salary at the rate of £50 per annum, with board, residence, and washing.

ROXBURGH DISTRICT ASYLUM, Melrose, N.B.—Assistant Medical Officer. Salary £110 per annum, with board, lodging, and washing.

ST. THOMAS'S HOSPITAL.—Assistant Surgeon. Must be a Fellow of the Royal College of Surgeons of England.

SCHOOL BOARD FOR LONDON—EVENING CONTINUATION SCHOOLS.—Lecturers and Examiners in First-Aid and Home Nursing. Qualified practitioners (men and women). Apply to the Clerk of the Evening Continuation Schools Committee, School Board for London, Victoria Embankment, W.C.

THE CHIEF INSPECTOR OF FACTORIES gives notice of vacancies for Certifying Surgeons under the Factory Acts at Bugbrooke, in the County of Northampton; at Petworth in the County of Surrey; at Nuneaton in the County of Warwick; and at West Linton in the County of Peebles.

TIVERTON (DEVONSHIRE) INFIRMARY AND DISPENSARY.—House Surgeon. Salary £80 and all found.

WESTERN GENERAL DISPENSARY, Marylebone-road, London.—Second House Surgeon, unmarried. Salary £75 per annum, with 10s. per month for washing, and board and residence.

WESTMINSTER HOSPITAL.—Obstetric Physician and also Assistant Obstetric Physician.

YORK DISPENSARY.—Resident Medical Officer, unmarried. Salary £110 a year, with board, lodging, and attendance.

Births, Marriages, and Deaths.

BIRTHS.

ANDREW.—On Jan. 9th, at Hendon, N.W., the wife of F. W. Andrew, M.R.C.S., L.R.C.P., of a daughter.

COLLARD.—On Jan. 13th, at Croydon, the wife of Stuartson Collard, F.R.C.S. Eng., of a daughter.

FOUNTAIN.—On Jan. 12th, at Arlington-park, Gunnersbury, W., the wife of R. Osborne Fountain, M.D., of a daughter.

GEORGE.—On Jan. 8th, at Port Isaac, Cornwall, the wife of R. Julyan George, M.D., of a son.

McDOUGALL.—On Jan. 12th, at Woodcote-road, Wallington, Surrey, the wife of William Stewart McDougall, M.B., C.M., of a son.

MORGAN.—On Jan. 16th, at 24, Grove Park, Camberwell, S.E., the wife of W. Ellis Morgan, M.R.C.S., L.R.C.P., L.M., of a daughter.

NOBLE.—On Jan. 13th, at Grove-road, Walthamstow, the wife of W. G. Noble, Surgeon, of a daughter.

PANTING.—On Jan. 10th, at Harvey House, Watton, Norfolk, the wife of John Panting, M.A., M.D., of a son.

PENFOLD.—On Jan. 10th, at Brownhill-gardens, Catford, the wife of Surgeon E. A. Penfold, R.N., of a daughter.

SARGENT.—On Jan. 11th, at 300, Commercial-road, E., the wife of G. E. H. Sargent, L.S.A. Lond., of a daughter.

TEBB.—On Jan. 15th, at 226, Finchley-road, Hampstead, Bertha, the wife of Albert E. Tebb, M.D., B.S. Lond., M.R.C.S., D.P.H., &c., of a son.

WESTBROOK.—On Jan. 14th, at Old Town, Clapham-common, S.W., the wife of Ernest Westbrook, L.R.C.P., of a son.

WHITCHER.—On Jan. 11th, the wife of Dr. Charles Edgar Whitcher, of Hove, Sussex, of a son.

MARRIAGE.

BOYCE—JOHNSTON.—On Jan. 9th, at Bromborough parish church, Cheshire. Robert William Boyce, M.B., Professor of Pathology, Liverpool University College, to Kate Ethel Johnston, second daughter of William Johnston, of Woodslee, Bromborough, Cheshire.

DEATHS.

CLAPPERTON.—On Jan. 10th, aged 60, James Clapperton, M.D., Broughton, Hampshire.

GODDARD.—On Jan. 13th, at his residence, Highbury New-park, N., Eugene Goddard, M.D., son of the late Leonard Morse Goddard, M.R.C.S., of Clerkenwell, aged 60.

JACKMAN.—On Jan. 11th, at 19, Wood View-gardens, Highgate, Thomas Smith Harrison Jackman, M.R.C.S. Eng., and L.R.C.P. Lond., late of 11, Stoke Newington-road.

HALIDAY.—On Jan. 10th, at Thicket-road, Anerley, Saunders Barton Haliday, Surgeon-Lieutenant-Colonel, Indian Medical Service, aged 57.

LEUMANN.—On Jan. 7th, suddenly, Bernard Henry Frederick Leumann, M.B, of Stanley-park-road, Wallington, in his 32nd year.

SYMES.—On Jan. 14th, J. G. Symes, M.R.C.S., &c., Southfield, Weymouth, in his 76th year.

TINLEY.—On Jan. 10th, at Sandsend, near Whitby, Thomas Tinley, M.D., J.P., aged 55 years.

WAYLEN.—On the 10th inst., at Guildford, Western Australia, Alfred Robert Waylen, M.D., late Colonial Surgeon, eldest son of the late Alfred Waylen of Devizes, Wilts, and of Perth, Western Australia, aged 67.

N.B.—A fee of 5s. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Short Comments, and Answers to Correspondents.

MEDICAL ATTENDANCE ON WORKMEN.

TWO medical men practising at Bromley were obliged recently to have recourse to the county-court in order to obtain payment from a firm of timber merchants for attendance in the case of a workman who was injured in the course of his employment. The medical men appear to have on a previous occasion asked some question as to who was to remunerate them in the case of such accidents and to have received som vague answer from a person not clearly authorised to give it to the effect that it would be "all right," and evidence of this having been given His Honour Judge Emden seems to have been satisfied with it as evidence of a promise to pay, while he appears to have expressed in pretty plain terms his view of the defendants' conduct and to have laid particular stress upon their duty to make a definite arrangement as to the medical aid to be afforded to their workpeople in the case of accidents. The case was eventually settled, the plaintiffs accepting five guineas and costs to prevent further delay in the conclusion of the matter. The trial points to the difficulty which besets the medical man called in on an occasion of some urgency without a definite understanding as to the payment of his fees. It is often almost impossible to obtain a satisfactory undertaking with regard to them at the time when the service is rendered. Self-respecting firms take steps to have the business side of the transaction completed before the necessity for medical help arises.

THE REAFFORESTING OF IRELAND.

THE part which the vegetable kingdom plays in the economy of the life of man is generally recognised, but the connexion between arboriculture and the prosperity of a country is not so widely appreciated. Dr. Robert T. Cooper has published a pamphlet which deals with the neglected condition of arboriculture in Ireland, and this he is prepared to regard as the real grievance of that country. He pleads for a better study of the question in order that the British Government may be induced to reafforest the 2,000,000 or more acres of mountain land which at the present time are unproductive and subserve in no way to human interests He points out that trees are a natural agency for the diminution and even for the prevention of the ill-effects of all kinds of climatic vicissitudes. Large portions of the upland surfaces, now practically bare rocks, might if grown over with trees be sheltered from rain and storm and form important catchment areas for the supply of rivers, &c. Moreover, the roots of the trees growing in such positions bring about the cleavage of rocks and cause fissures through which the rain finds its way to underground strata, which, becoming subcharged with moisture, discharge their overflow in the form of springs of naturally filtered water. The decay of the vegetation and the action of its contained acids upon the rock naturally form a rich manurial mould which is slowly washed down to the low-lying expansions of the country. Torrential streams would disappear and rivers would be purer, floods less frequent, and bog slides rare. We cannot endorse the suggestion that a Hibernian millenium would follow upon systematic tree-planting in Ireland, but we found Dr. Cooper's pamphlet, which was part of a lecture delivered in the Rotunda Rooms last autumn, very interesting reading.

"PROFESSOR EASTBURN, A.M.S."

THE crimp who used to swindle seamen out of their wages and clothing is, we fancy, nearly, if not quite, extinct; but there are worse swindlers than crimps who not only rob people of money but of their health in addition. We are led to these remarks by a letter which we have received from a medical man inclosing a letter which was received by a patient of his, a seaman who has been foolish enough to apply for treatment to a quack "practising" in Glasgow and calling himself Professor Eastburn, A.M.S. Eastburn's letter is adorned with a portrait, presumably of himself, together with an eagle and the Stars and Stripes, so we presume that he claims to be a citizen of the United States. Our correspondent informs us that his patient suffered from chronic gleet, that he wrote to Eastburn and received in reply a string of questions to answer, and that he paid £11 for four months' treatment. The medicine was always the same and upon the patient writing to say that he was not improving Eastburn replied, "Continue the same medicine and send more money to complete the £14 originally arranged for." Our correspondent adds that his patient received six bottles of medicine for his £11 and that Eastburn's fee to wealthy patients is from £40 to £50, but that the lowest sum for which he undertakes a case is £14. We cannot see why the legislature, which is rightly hard upon thieving should not find some way of putting down swindlers of this description. Such frauds are, in addition to their dishonesty, cruel to a degree. Eastburn is said to do a large business with seamen trading to and from Glasgow.

"VACCINATION FEES."

To the Editors of THE LANCET.

SIRS,—In THE LANCET of Dec. 22nd, 1900 (p. 1854), under your Answers to Correspondents, you have given a reply to "Public Vaccinator" which I think is hardly correct. You state that a public vaccinator is not entitled to charge 1*s* birth fee for children under four months vaccinated by himself. Upon reference to the Vaccination Order, 1898, Article III., Sec. 2, the law says: "The number of children in respect of whom payments are to be made under paragraph (*a*) of this article shall be the number of children in the lists to be sent by the vaccination officer to the public vaccinator as provided by paragraph 6 (*a*) of the Instructions to Vaccination Officers in the Fourth Schedule hereto, together with the number of children not included in such lists but vaccinated by the public vaccinator himself." This matter was pointed out to my guardians by the auditors and they have consequently paid me every quarter as above, and I should advise your correspondent "Public Vaccinator" to insist on payments being made to him. At the end of each quarter my guardians give me a list of children who have been reported by me on Form H as "postponed," with a request that I should continue to visit the children and report further. I maintain they have no authority to make this request and I have lately refused to observe the same. May I ask: 1. What should be done by the public vaccinator when a case has been postponed, say, one month? Is it his duty to call again, for there are no instructions in the Act for any other than the original visit? 2. What should be done by the public vaccinator if when he makes his pre-arranged visit he finds the door locked? 3. Have the guardians any authority to give orders to the public vaccinator which are not included in his original contract with them?

I am, Sirs, yours faithfully,

Jan. 9th, 1901. ANOTHER PUBLIC VACCINATOR.

THE PROGRESSIVE MEDICAL ALLIANCE AND OTHERS.

IN our issue of Sept. 29th, 1900, p. 981, we reprinted the greater portion of a four-page hand-bill issued by the Progressive Medical Alliance and suggested that the General Medical Council might take some notice of the graduates of British Universities whom the Alliance claims to have upon its staff and also of the lady physician. We have now received another bill of the Progressive Medical Alliance through a medical man who had it from one of his patients, the bill having been passed under the door of the patient's house. Coincidently we received from a second medical man the following bill emanating from an independent practitioner which had also been pushed under the door of the house of a patient of his:—

"Consultation, with or without medicine, One Shilling; Medicine 6*d.*
Examination, with or without certificate, Half-a-crown for Clubs, Insurances or other Societies.
At home Nine to Eleven o'clock every morning, at Three o'clock every Afternoon; and Seven to Eight o'clock every evening.
Sundays after 6 o'clock. Forenoon by Appointment.
Medicine and Attendance, Half-a-crown each week or part of a week.
No further charge for the remainder of the week. Seven days to the week, commencing at any time.
Vaccination, One Shilling; from Calf Lymph, Half-a-crown.
Teeth Extracted One Shilling each; Painless, Half-a-crown.
Teeth Stopped Half-a-crown each; and Artificial Teeth, One Guinea the Set.
Visiting Payments after Ten o'clock at Night, and before Eight o'clock in the Morning, according to time and distance.
Attendance includes Visits when patients are not able to attend at the Doctor's Surgery.
Midwifery, Accouchements, Confinements, Half-a-guinea. Fifteen shillings, One Guinea, and Two Guineas, according to agreement beforehand, when half the fee must be paid. The fee includes One week's after attendance and medicine.
Drugs, Medicines, and Proprietary Articles at Cash Prices.
Diseases of Women and Children attended.
Apply—
DR. ——,
Physician, Apothecary, Accoucheur and Surgeon.

Teeth Extracted, at any hour guaranteed painless.
The above are only for Cash payments, paid in advance."

Now, the Progressive Medical Alliance is obviously a quack association of the worst type and we think that no greater reproof could be given to a qualified man than to put on record the fact that he advertises himself in the same way as the Progressive Medical Alliance. We advise the correspondent who sent us the circular to communicate with the University from which Dr. —— received his degree. For this occasion we have withheld the offending practitioner's name, but we shall give him full publicity if his methods remain unaltered.

NEW DOMESTIC FILTERS.

WE have received from the London and General Water Purifying Company, Limited, of 157, Strand, W.C., two new designs in domestic water filters. One is described as a pump filter which consists of a pump connected with a filter tube of unglazed porcelain which has been shown to be in a series of severe bacteriological experiments germ-proof, yielding a filtrate absolutely sterile. The many valuable sanitary applications to which this portable filter may be put are obvious. The other filter is a main-service filter which may be connected directly with the supply. This consists of a small metal chamber, bell-shaped, packed with small pieces of marble and closed at the top with a disc of unglazed porcelain consisting of the same germ-proof material of which the pump-filter is made. Both filters are made in accordance with modern views on the subject, but we hope shortly to submit them to independent experiment with the view of being able to state their actual efficiency.

WANTED—A HOME.

To the Editors of THE LANCET.

SIRS,—Can any of your readers inform me of a home or institution where a long-standing (four years) case of hysteria in a young man might be treated at a small expense? I shall be much obliged.

I am, Sirs, yours faithfully,

Jan. 8th, 1901. YOUNG PRACTITIONER.

"THE CASE OF DR. PATRICK QUINLIVAN."

THE following further subscriptions have been received towards the fund on behalf of the widow of the late Dr. Quinlivan. The fund is now closed. Dr. C. Y. Pearson (Cork), £1 1*s.*; Mr. W. A. Farebrother, £1 1*s.*; Mr. Holland Wright, £1 1*s.*; C. F. W., 10*s.*

G. P.—There can be no hard-and-fast rules in the matter. The medical officer to a medical aid association has to remember that he must not take advantage of the position to advertise himself in any way at the expense of his brother practitioners. Any wide publication of his titles on door-plates or in circulars must be avoided, and as all canvassing on the part of the association is apt to be an advertisement of the medical officer he must in his own interests use his influence to prevent such proceedings.

J. A. D. can make inquiry in our columns for such a home, giving a name and address where answers will reach him. We do not know of any institution exactly meeting his wants.

Leicester.—The address of the Medical Defence Union is 4, Trafalgar-square, W.C. Dr. A. G. Bateman is the general secretary.

J. R. B.—The reports are published by Messrs. P. S. King and Son, London.

ERRATUM.—In an advertisement in THE LANCET of last week for an additional surgeon to the out-patient throat department of the Great Northern Central Hospital the Secretary points out that the word "and" was wrongly interpolated between the words "out-patient" and "throat department."

EDITORIAL NOTICES.

It is most important that communications relating to the Editorial business of THE LANCET should be addressed *exclusively* "TO THE EDITORS," and not in any case to any gentleman who may be supposed to be connected with the Editorial staff. It is urgently necessary that attention be given to this notice.

It is especially requested that early intelligence of local events having a medical interest, or which it is desirable to bring under the notice of the profession, may be sent direct to this Office.

Lectures, original articles, and reports should be written on one side of the paper only, AND WHEN ACCOMPANIED BY BLOCKS IT IS REQUESTED THAT THE NAME OF THE AUTHOR, AND IF POSSIBLE OF THE ARTICLE, SHOULD BE WRITTEN ON THE BLOCKS TO FACILITATE IDENTIFICATION.

Letters, whether intended for insertion or for private information, must be authenticated by the names and addresses of their writers, not necessarily for publication.

We cannot prescribe or recommend practitioners.

Local papers containing reports or news paragraphs should be marked and addressed "To the Sub-Editor."

Letters relating to the publication, sale, and advertising departments of THE LANCET *should be addressed "To the Manager."*

We cannot undertake to return MSS. not used.

MANAGER'S NOTICES.

THE INDEX TO THE LANCET.

THE Index to Vol. II. of 1900, which was completed with the issue of Dec. 29th, and the Title-page to the Volume were given in THE LANCET of Jan. 5th.

VOLUMES AND CASES.

VOLUMES for the second half of the year 1900, bound in cloth, gilt lettered, price 18*s.*, carriage extra

Cases for binding the half-year's numbers, cloth, gilt lettered, price 2*s.*, by post 2*s.* 3*d.*

To be obtained on application to the Manager, accompanied by remittance.

TO SUBSCRIBERS.

WILL Subscribers please note that only those subscriptions which are sent direct to the Proprietors of THE LANCET at their Offices, 423, Strand, W.C., are dealt with by them? Subscriptions paid to London or to local newsagents (with none of whom have the Proprietors any connexion whatever) do not reach THE LANCET Offices, and consequently inquiries concerning missing copies, &c., should be sent to the Agent to whom the subscription is paid, and *not* to THE LANCET Offices.

Subscribers, by sending their subscriptions direct to THE LANCET Offices, will ensure regularity in the despatch of their Journals and an earlier delivery than the majority of Agents are able to effect.

The rates of subscriptions, post free, either from THE LANCET Offices or from Agents, are:—

FOR THE UNITED KINGDOM.		TO THE COLONIES AND ABROAD.	
One Year	£1 12 6	One Year	£1 14 8
Six Months	0 16 3	Six Months	0 17 4
Three Months	0 8 2	Three Months	0 8 8

Subscriptions (which may commence at any time) are payable in advance. Cheques and Post Office Orders (crossed "London and Westminster Bank, Westminster Branch") should be made payable to the Manager, MR. CHARLES GOOD, THE LANCET Office, 423, Strand, London, W.C.

SUBSCRIBERS ABROAD ARE PARTICULARLY REQUESTED TO NOTE THE RATES OF SUBSCRIPTIONS GIVEN ABOVE. It has come to the knowledge of the Manager that in some cases higher rates are being charged, on the plea that the heavy weight of THE LANCET necessitates additional postage above the ordinary rate allowed for in the terms of subscriptions. Any demand for increased rates, on this or on any other ground, should be resisted. The Proprietors of THE LANCET have for many years paid, and continue to pay, the whole of the heavy cost of postage on overweight foreign issues; and agents are authorised to collect, and do so collect, from the Proprietors the cost of such extra postage.

The Manager will be pleased to forward copies direct from the Offices to places abroad at the above rates, whatever be the weight of any of the copies so supplied. Address—THE MANAGER, THE LANCET OFFICES, 423, STRAND, LONDON, ENGLAND.

During the week marked copies of the following newspapers have been received: *Devon and Exeter Express, Burnley Express, Ulster Echo, Manchester Dispatch, Glasgow Citizen, Bradford Observer, Darlington Star, Sheffield Daily Telegraph, Blackburn Gazette, Bournemouth Guardian, Glasgow Times, Manchester Courier, Dudley Herald, Northern Guardian, Lancashire Post, Bristol Times, Leeds Mercury, Grantham Journal, Plymouth Morning News, Western Mercury, Yorkshire Post, Ipswich Times, Times of India, Pioneer Mail, Citizen, Architect, Builder, Blyth News, Weekly Free Press (Aberdeen), Bristol Mercury, Scotsman, Brighton Guardian, Leighton Buzzard Observer, West Times (Exeter), Englishman (Calcutta), Madras Journal, Reading Mercury, Mining Journal, City Press, Local Government Chronicle, Hertfordshire Mercury, Sanitary Record, The Record, Torquay Times, Nuneaton Chronicle, Black and White, Derbyshire Courier, Surrey Advertiser, Local Government Journal, Carpenter and Builder, Rotherham Express, Bromley and West Telegraph, North Star (Darlington), St. John's Telegraph (N.B.), Liverpool Daily Post, &c., &c.*

An original and novel feature of "THE LANCET General Advertiser" is a Special Index to Advertisements on pages 2 and 4, which not only affords a ready means of finding any notice, but is in itself an *additional* advertisement.

Advertisements (to ensure insertion the same week) should be delivered at the Office not later than Wednesday, accompanied by a remittance.

Answers are now received at this Office, by special arrangement, to Advertisements appearing in THE LANCET.

The Manager cannot hold himself responsible for the return of testimonials, &c., sent to the Office in reply to Advertisements; copies only should be forwarded.

Cheques and Post Office Orders (crossed "London and Westminster Bank, Westminster Branch") should be made payable to the Manager, Mr. CHARLES GOOD, THE LANCET Office, 423, Strand, London, to whom all letters relating to Advertisements or Subscriptions should be addressed.

THE LANCET can be obtained at all Messrs. W. H. Smith and Son's and other Railway Bookstalls throughout the United Kingdom. Advertisements are also received by them and all other Advertising Agents.

Agent for the Advertisement Department in France.—J. ASTIER, 8, Rue Traversière, Asnières, Paris.

An Address

ON

THE SELECTIVE INFLUENCE OF POISONS IN RELATION TO DISEASES OF THE NERVOUS SYSTEM.

Delivered before the Nottingham Medical Society on Oct. 10th, 1900.

By FREDERICK W. MOTT, M.D. Lond., F.R.S.,
PATHOLOGIST TO THE LONDON COUNTY ASYLUMS; PHYSICIAN IN CHARGE OF OUT-PATIENTS TO CHARING CROSS HOSPITAL.

GENTLEMEN,—When your President did me the honour of asking me to give an address to the Medical Society of this city I accepted upon the condition that he should suggest a subject. He kindly replied that he thought something concerning the "new neurology" would be acceptable.

The term "new neurology," however, is correct and it is incorrect. It is correct inasmuch as this science is progressive, yet it is incorrect because the new neurology began half a century ago with the cellular theory of Virchow and the neuron theory foreshadowed by Waller, and within the last 20 years again revived, expanded, and applied, as Waller had indicated it would be, to the explanation of disease. With the revival of the theory of the trophic and genetic independence of every nervous unit or neuron has grown up a new pathology of the nervous system, depending not only upon the neuron theory but also upon the fact that every cell possesses a bio-chemical sensitiveness to its lymph-environment termed "chemiotaxis." It is the failure of the neuron under the influence of an altered environment, or owing to inherent vital prostration to carry on the processes of assimilation and dissimilation which are essential for the well-being of every cell, that is the essential cause of a class of diseases of the nervous system which include functional diseases and primary degenerations. These are primary diseases of the nervous system as distinct from diseases within the nervous system; and by the latter I mean those diseases which arise primarily from affections of the blood-vessels supporting and inclosing tissues, causing secondary changes in the nervous elements—familiar examples of which are afforded by the destruction of nervous tissue caused by hæmorrhage, thrombosis, and embolism, by tumours, injury, and diseases of the membranes and neuroglia tissue. The symptoms are usually coarse, random, and dependent upon mechanical disturbances of the circulation—often sudden in onset, and in most of these conditions non-progressive; whereas the primary intoxications and degenerations are, as a rule, symmetrical, related rather to the functions of groups, systems, and communities of neurons, and occasioned directly or indirectly by some general toxic condition of the blood or lymph. It is to this latter class of affections of the nervous system that I shall particularly draw your attention this evening.

Although the toxic substance circulating in the blood must come into contact with all the neurons equally, yet we find that in a great number of instances particular groups, systems, and communities of neurons, subserving special functions, are especially and, indeed, not infrequently solely affected by particular poisons. It is this selective action of certain poisons which impresses upon our minds a clinical picture that enables us in a great number of instances to recognise the cause by the character of the symptoms. In illustration thereof I need only cite tetanus and rabies. Although it must be admitted that in every form of intoxication of the nervous system individual temperament may vary the complexion of the symptoms to some extent, poisons like tetanus and strychnia have a specific action upon the spinal motor neurons and act upon all individuals in practically the same manner, whether such contributory factors as inherited neurosis, or psychosis, stress, or vascular congestion be present or not.

There are, however, a great number of functional and organic diseases of the nervous system in which poisons circulating in the blood act as contributory, predisposing, or exciting causes to persons with a neuropathic or psychopathic heredity, also to persons who have subjected their nervous system to excessive functional activity or stress. These three factors, *toxæmia*, *stress*, and *hereditary neurosis or psychosis*, combine to form a vicious circle in a majority of cases—a vicious circle which is continually extending its limits and which can alone be broken by removal of one or more of these three factors. Obviously, in the individual, only the first two are capable of withdrawal. The fundamental biological principles underlying all protoplasmic activity, whether it be that of a single independent unit, or the marvellous aggregation of cells or derivatives of cells constituting the human organism, are (1) the preservation of the individual, and (2) the perpetuation of the species, and this is a truism even when applied to the most complex psychical phenomena. Just as the individual is continually striving to adapt himself to his environment, so every individual component cell of the body is striving to adapt itself to its fluid lymph environment. This can only be effected by the harmonious coöperation of the whole, insuring a constant stream of blood of uniform quality whereby physiological metabolic equilibrium is maintained. The nervous system not only serves in maintaining the relation of the individual to his external environment in response to present or past stimuli from without, but it also serves to correlate all the internal activities of the tissues and organs of the body by stimulating here, inhibiting there, and distributing the blood to the tissues in proportion to their activity. The nervous system is enabled to control the activities of all the tissues of the body by impressions conveyed to and from them by nerve fibres to and from various centres; but we also know that the nerve centres themselves are bio-chemically sensitive to the state of the blood occasioned by an organ which is diseased, when all the nervous paths from the organ have been interrupted. The essential property of the nervous elements or neurons is excitability; and poisons act upon the nervous system by increasing or diminishing the excitability of the nervous elements or neurons. Thus poisons which produce motor phenomena produce exciting or convulsive and paralytic or depressing phenomena. Whether a given poison will excite or depress function largely depends upon the dose. Many exciting poisons in small doses produce convulsive effects, but in larger doses depressing effects. The converse is also true of many depressing poisons. Directly or indirectly all poisons act injuriously upon the organism through the nervous system, and nature has provided many defensive means to combat the introduction of poisons from without. Taste and smell are special senses which stand as sentinels to the alimentary and respiratory tracts and generally enable us to avoid the introduction of poisons into the body, although they do not allow us to avoid auto-intoxication or the escape of poisonous products into the blood owing to perverted function of the organs or tissues of the body. One of the most important and dangerous sources of poisons acting upon the nervous system is that due to the growth of microbes, and while the products of microbial growth are usually such as to give rise to unpleasant smells, a certain number of pathogenic organisms—e.g., cholera, typhoid, bacillus botulinus, and enteritidis—may enter the body without being detected by taste or smell. The chemical substances elaborated by the growth of some pathogenic organisms absorbed into the blood provoke vomiting and diarrhœa of central origin—an attempt on the part of the body to eliminate the noxious agent; but these defensive measures, which are of a reflex nervous nature, are insufficient, and another mode of defence is provided by the vital activities of the tissues themselves—viz., the secretion of antitoxins, which not only serve to neutralise the chemical products of the organisms but to paralyse and destroy the vital activities of the microbes themselves. Another defensive action on the part of the tissues is a gradual tolerance of the tissues to perform their functions even with a poisoned environment, and as we shall see later in considering the *habit poisons* the toxic environment of the nervous elements may be in time the condition under which they can best perform their functions. I have already remarked that the functions of the neuron depend upon its excitability—i.e., a bio-physical property by which it is capable of a molecular vibration which is propagated through its protoplasmic substance along definite lines. We speak of a nerve impulse being "cellulipetal" or "cellulifugal," according as the impulse is conducted to or from the cell. Every neuron or nervous unit consists of a cell body and processes, one of which only becomes the axis-cylinder

of a nerve. The whole nervous system consists of these independent cellular units, and although there may be differences of opinion as to whether one nervous unit is connected with another by its branching processes—i.e., a direct protoplasmic continuity—there can be no doubt that each neuron was developed from a separate cell and is therefore genetically independent. The degenerations arising either from injury or disease being limited to definite systems and groups of neurons show, moreover, that they are nutritionally independent. Therefore we are justified in supposing that every neuron acts as an independent organism, has a specific vital energy, and possesses a store of potential upon which the function of excitability depends. If the nervous system is in a normal physiological condition the protoplasm of the neurons is in a state of bio-chemical stability whereby the processes which underlie conversion of potential into active energy under the influence of stimuli are so adjusted that the response is apportioned and appropriate to the stimulus, and there is no tendency for the impulse to act as a fulminant.

Potential energy depends upon the activity of the protoplasm and the maintenance of the balance between constructive and destructive metabolism, but the balance of potential varies in every individual, according to the bio-chemical stability of the nervous elements as a whole or in part. Thus, in neurasthenia, potential is low because the processes of assimilation do not bear a proportional value to dissimilation. The nervous elements suffer essentially only from two morbid conditions—viz., increase of excitability and tendency to fulminate or spread, and diminution or loss of excitability. In the case of motor neurons the two conditions are exhibited respectively by convulsive or tonic muscular spasm and paralysis; in the case of sensory neurons by hyperæsthesia and anæsthesia; but every group of neurons is functionally correlated with other groups, and paralytic phenomena occurring in one group will allow the opposing correlated group to overact; in fact, as Dr. Hughlings Jackson has pointed out, it is not too much to assert that one-half of the symptoms of nervous disease are due to physiological overaction of unopposed nervous influences, and if a poison entering the system has a selective action upon some particular group of neurons, paralysing their function, then an opposing group, which may be functionally depressed, will appear to be over-active. We shall see that this applies not only to such physical phenomena as double vision, a consequence of squint, and of contracture on account of paralysis, but the truth of the dictum may be applied to perverted mental processes—in fact, there is a similarity between a fixed idea and a limb in contracture.

Poisons are either introduced into the body from without or produced within (exogenetic or autogenetic). In either case it is the toxic state of the blood or lymph which causes the morbid nervous phenomena, and the symptoms which arise are dependent upon conditions of either increased excitability or depressed excitability of the nervous elements. We have seen that in one case the selective influence of the poison upon particular nervous structures is dependent upon the chemical properties of the poison itself. It has a specific action, whereas in the other case the poison selects particular structures in the nervous system owing to an inherited or acquired low potential of the nervous elements or an instability of their protoplasm. The poisonous alkaloids, such as strychnia, curare, atropine, muscarine, and pilocarpine, show that they owe their toxic properties to the chemical affinity which certain nervous structures have for these poisons, causing excitation or depression of their function.

But I will particularly call your attention to a series of poisons which have served human beings in various lands to satisfy a strange need of altering and transforming the physiological processes of the mind and of withdrawing themselves from the real world in which they live, by the abuse or daily indulgence of various intoxicant substances introduced into the body in various ways—viz., alcohol, opium, haschish, morphia, cocaine, tobacco, and absinthe, each of which may be characterised by perversion or disturbance of the higher functions of mind, although each drug shows by the specific toxic effects which it produces a different mode of action. As, however, I have previously indicated, individual temperament may impress a special colour on the complexion of the symptoms. The features of acute alcohol poisoning are but too well known. As Maudsley aptly says, "A man in the process of getting drunk displays an abstract and brief chronicle of insanity, going through its successive phases in a short time." In every mental process the whole cerebral cortex is engaged, but it appears probable that certain projection fields or identification centres may under the influence of different toxins be excited or their functions disturbed and perverted in a characteristic manner. Thus visual and auditory hallucinations of a horrid or terrifying character are especially frequent in acute alcohol poisoning, whereas alcohol is indulged in by a large number of people to banish sorrowful recollections, to drown dull care and present troubles. How often it is extremely difficult to decide whether a patient is suffering from *mania à potu*, pure and simple intoxication, or true mania with alcoholism—and especially does this apply to the mania of general paralysis. No doubt such cases have presented themselves to most of the busy practitioners forming my audience, but perhaps I may be permitted to describe the symptoms of an unusual case, for they illustrate this peculiar toxic influence of alcohol.

A man was admitted to an asylum who presented all the symptoms of alcoholic delirium. He had visual hallucinations in the form of black devils which came and perched upon his nose and which emitted foul smells and introduced bitter poisons into his mouth. He would continually move his hand as if to flick them away. The pupils were unequal and there was reflex iridoplegia, with syphilitic chorioretinitis. I therefore came to the conclusion that it was general paralysis with acute alcoholic intoxication, for the patient smelt of drink and there was a very marked history; in fact, he was admitted as a drink case. A week later when I saw him the toxic effects of the alcohol had had time to pass off and he now had an exalted expression and said that angels came and sat on his nose and moistened his lips with honey and breathed sweet perfumes into his nostrils. Possibly an autotoxin may be the cause of the grandiose delirium of this disease.

The mental process by which time and spacial relationship is estimated, depends primarily upon the kinæsthetic sense, although higher controlling centres, existing in the pre-frontal lobes probably coöperate. The primary kinæsthetic ideation centres are situated in the frontal and central convolutions, in which are located not only the efferent neurons which preside over voluntary movements of all the muscles of the body, but also they are the seat of the terminal neurons of the afferent projection system, in which every movement and change of position by muscular action is registered by means of tactile motor sensations coming from skin, muscles, joints, and tendons. Haschish, a poison which is used in Eastern countries and is a common source of insanity, has, it is said, very curious characteristic effects upon perception in this tactile motor ideation centre, for it may produce the most remarkable illusions relating to the notion of space and time. External objects appear extremely enlarged in all their dimensions and time appears indefinitely prolonged. Morphia, like alcohol and absinthe, leads to increased ideation and loss of control of ideas, only much more marked; in fact, control entirely disappears and one idea succeeds another with extraordinary rapidity, each one calling up another without the possibility of staying them. It is persistent and uncontrollable ideation; the highest level centres are depressed, the middle level centres are exalted. It has been affirmed that the weirdly vivid imagination of De Quincey was in a measure due to the opium habit in which he indulged. An interesting physiological fact in connexion with these psychical poisons is that habit renders the abnormal toxic environment of the neuron the normal. Morphia, which has been the best studied and offers the best example in this respect, shows that through long use the state of morphia intoxication may become the normal state of the brain of the individual, so that under this condition only are the nervous elements able to carry on physiological processes of assimilation and dissimilation and perform their functions, for sudden withdrawal of the poison can bring about delirium, hallucinations, and other mental symptoms. There is thus an analogy between the intoxication of the normal brain and the sudden non-intoxication of a brain which, habituated for a long time to a morphinised environment, has adapted itself accordingly.

Of all the extrinsic causes of nervous and mental diseases the abuse of alcohol is the most widespread and potent, for at least 20 per cent. of the inmates of the London county asylums are suffering directly or indirectly from the effects of the abuse of alcohol. Most of these patients, however, have an inherited neuropathic or psychopathic taint, and my

experience as pathologist during the last five years supports the conclusion that alcohol may, in comparatively small quantities or indulged in for comparatively short periods of time, produce in people with an unstable mental organisation marked toxic effects. The effect on the nervous system of chronic alcoholism is dementia, a very characteristic manifestation of the mental degradation being absence of knowledge of time and place and loss of memory, especially for recent events, with personal illusions, indicating a failure of receptivity and the formation of memory pictures in the higher ideation centres. A certain amount of improvement may occur when total abstinence is enforced, which shows that the poison has damaged, but not entirely destroyed, the nervous elements. In cases, however, where the dementia is permanent organic changes may be found in the brain—viz., an atrophy of the tangential, super-radial, and inter-radial association fibres, structures which are usually found damaged in all cases of organic dementia. Besides mental symptoms of alcoholic poisoning there is very frequently, and especially in women, paralysis affecting the lower limbs, although the upper limbs, and even the heart and respiratory muscles—in fact, all the muscles of the body—may be affected in severe cases. The patient becomes helpless and bedridden and death occurs frequently from heart or respiratory failure. Characteristic features of this affection are great tenderness on pressure, especially of the calves, absence of reflexes, a variable degree of skin anæsthesia affecting especially the apices of the limbs, wasting of muscles, alteration of the normal electrical reactions, and frequently pyrexia, but there is no loss of control over the sphincters unless there is dementia. This complex of symptoms points to a peripheral polyneuritis, although marked changes may be usually found by certain methods of staining in the ganglion cells from which the axis-cylinders take their origin. I have endeavoured in the Croonian Lectures to give an explanation of why the extremities of the limbs are most affected as regards movement and sensation and why the effects of the poison as they become more marked lead to the defect in sensation and movement, travelling up the legs towards the centre in the manner one puts on a stocking, and as the effects of the poison wear off sensation returns in the manner one takes off a stocking.

Many other poisons—lead and arsenic, toxins of the acute specific fevers, and toxic states of the blood due to imperfect metabolism, such as occurs in diabetes and gout—may produce, or become an important factor in producing, peripheral neuritis. It is asserted that the toxic amblyopia with central scotoma of tobacco poisoning is due as much to the alcohol as the nicotine, but although it cannot be denied that alcoholic intemperance tends to induce this condition, yet it is certain that tobacco taken in any form by certain individuals has a selective toxic action upon the neurons of central vision. An argument in favour of this is in the case recorded of horses which had eaten the tobacco plant and suffered with amblyopia. Lead is peculiar in selecting the nerve which supplies the extensor muscles of the wrist and fingers, so that dropped wrist is almost characteristic of this form of toxic neuritis; but lead also produces changes in the brain, encephalitis saturnina, a complex of symptoms including dementia, loss of memory, weakened intellect, paresis, and epileptiform seizures, hallucinations of sight and hearing, and mental exaltation or depression. Large numbers of people in Northern Italy and Egypt suffer with pellagra, an affection of the skin associated with degenerative changes in the brain and spinal cord. The people so affected suffer generally from a fatuous melancholy and suicidal impulses, and sometimes from mania. It is supposed that this disease is due to the bad maize upon which the people at times have to subsist. There is also ergotism, a disease which is due to poor people in Russia and Northern Germany being obliged, owing to the failure of the rye crop, to subsist upon bread made from grain which has been attacked by the ergot fungus. The poison thus introduced into the system produces progressive degenerative changes in the brain and spinal cord, which are manifested by psychical disturbances, such as slowness of thought, weakness of memory, dulness of perception, sometimes delirium and incoherence, and other symptoms such as blunted sensibility, dilated pupil, muscular spasms, ataxy, and epileptiform fits, frequently terminating in stupor, coma, and death. The symptoms in both these diseases are due to progressive degenerative changes in the brain and spinal cord, the changes in the latter being closely allied to the changes met with in cases of pernicious anæmia and grave anæmia, which I shall have occasion to refer to later. An acute disease, the symptoms and fatal results of which are due doubtless to the action of a specific toxin upon the neuron, is botulism, which arises from eating meat and fish infected with the bacillus botulinus. It was described first by Ermenghen, who discovered the organism in the food eaten by people who had died with a characteristic group of symptoms in which paralysis of the ocular muscles was an important symptom. The toxin produced by this organism has been separated by Ehrlich, and it is extremely virulent, the most minute dose being sufficient to produce fatal results. I shall show you the changes in the nerve-cells produced by this poison, and also the fatty degeneration of the muscle which occurred after an extremely small fatal dose had been administered, so that an animal was able to survive the effects of the poison for eight days, thus allowing this change to take place. I could cite a number of other poisons which may enter the system from without and which would give rise to characteristic complex of symptoms did time permit.

I shall now pass on to the consideration of those poisons which are produced within the body (1) by the perverted functions of the organs or tissues, and (2) by the action of micro-organisms upon the living fluids and tissues of the body.

Certain normal constituents of the blood, e.g., carbonic acid, sarco-lactic acid, and the series of nitrogenous waste products, the highest oxidised, most soluble, and least harmful of which is urea, may accumulate in the blood, owing either to excessive production or defective elimination, and toxic environment of the neuron may supervene. Take, for example, uræmia, the nervous manifestations of which are headache, drowsiness, or unconsciousness, epileptiform convulsions, and sometimes symptoms of polyneuritis, showing, therefore, that the normal excitability of certain neurons (higher controlling) has been depressed, while that of others is increased through the effect of the poison. Graves's disease is possibly an example of an increased functional activity of a gland, giving rise to an increase of its secretion which, although essential, as myxœdema shows, for the proper metabolism of the body as a whole and of the brain in particular, yet when the secretion is in excess causes nervous phenomena in the form of exophthalmos, fine tremors, palpitation, tachycardia, and sometimes pyschical phenomena in the form of mania or melancholia. In the process of digestion a number of toxic albumoses and other substances are produced which, although absorbed in the alimentary canal, are prevented by the vital action of the lining epithelium and the bio-chemical processes occurring in the liver from entering the systemic circulation. If these structures are prevented by functional depression, inflammation, or disease from performing their normal functions, toxic conditions of the blood may arise and be a source of morbid nervous phenomena. Excess of uric acid in the blood is associated with high arterial pressure, probably owing to vaso-motor irritation, accompanied by deposits of lithates in the urine, headache, and nervous irritability; it is an indication of imperfect metabolism, as shown by the fact that marked improvement occurs by suitable diet and treatment. Phosphoruria, oxaluria, and glycosuria are all tokens of deranged metabolism and the circulation of blood of impure quality, and may be associated with various nervous disturbances. Cholæmia resulting from obstructive jaundice gives rise to psychical depression and may even be attended by stupor. The term "melancholia," signifying "black bile," indicates the importance which has long been attached to the liver as an organ, the derangement of which causes nervous depression. The rapidly fatal result preceded by delirium, motor irritation, delusions, stupor, and coma occurring in acute yellow atrophy of the liver demonstrates the important part which this organ plays in maintaining constant the normal quality of the blood. The delirium and coma which sometimes supervene in diabetes, heralded by acetonæmia, are another instance of auto-intoxication. Again, in pernicious anæmia and certain grave anæmias the characteristic combined sclerosis due to degenerative changes in the spinal cord found in many of these cases is due not so much to the defect in the red corpuscles as to some toxic agent absorbed into the portal blood from the alimentary canal which leads to hæmolysis and acts as a poison upon those nervous structures which are found in a state of degeneration.

Poisons circulating in the blood and lymph the products of infective micro-organisms which have established themselves in the body.—In the course of the acute infectious diseases and also the last stage of many general diseases delirium is a frequent complication. It may be explained by the fever, but I do not think, unless there is hyperpyrexia, that the rise of temperature is the cause so much as the toxic condition of the blood. "The last to come and the first to go" is an axiom which can be applied to the effects of toxic conditions of the blood in the production of delirium. The highest specialised controlling functions of the brain depend upon cortical systems of neurons, which are evolutionally and morphologically the latest developed, therefore are most readily affected by a poisoned environment, and vascular congestion or anæmia of the brain tissues observed post mortem and considered by some authorities to explain the symptoms are in reality merely accidental or concomitant conditions. Shakespeare, whose psychology will last for all time because it is the breath of humanity in all its varied aspects of health and disease, clothed in his own poetic language the cause and fateful omen of delirium in an infective disease:—

> The life of all his blood
> Is touched corruptibly: and his pure brain
> (Which some suppose the soul's frail dwelling house)
> Doth by the idle comments that it makes
> Foretell the ending of mortality.

Again, in his description of Falstaff's death he indicates the mental state of impending dissolution, for Dame Quickly says:—

> After I saw him fumble with the sheets and play with flowers and smile upon his finger ends I knew there was but one way, for his nose was as sharp as a pen and a babbled o' green fields.

Likewise the struggle between the poison and the defensive action of the tissues culminating in a supreme effort of the latter and the advent of the crisis was recorded in the words:—

> Before the curing of a strong disease,
> Even in the instant of repair and health,
> The fit is strongest: evils that take leave
> In their departure most show evil.

It does not always happen, however, that evils take their departure without leaving a scar, and various nervous and mental diseases may date their origin from an acute specific fever. Sometimes it may be a persistence of the nervous derangement which manifested itself during the course of the disease; more often, however, the toxæmia has produced a state of low potential or a state of bio-chemical instability in certain nervous structures; or it may happen that the poison may have contributed to the development of a scar in some inherited *locus minoris resistentiæ* of the nervous system, the result being that certain groups or systems of neurons are in a state either of depressed or increased excitability—i.e., there is a morbid condition in which the normal stimulus will not produce a response, or there will be a tendency for the tissue when acted upon by slight abnormal stimuli to fulminate. A certain number of cases of puerperal insanity, which usually occurs within a few days of delivery, are due to septic blood-poisoning in psychopathic or neuropathic individuals. Moreover, acute specific fevers occurring in persons suffering with epilepsy, whether idiopathic or from chronic brain disease, are ushered in by convulsive seizures, indicating the bio-chemical sensitiveness and instability of certain nervous structures in the brain to the altered state of the blood. Again, children in whom the higher inhibitory controlling centres are imperfectly developed, especially if there is any family neurosis, manifest he onset of an acute disease by convulsions.

The best examples of selective action of microbial toxins are afforded by rabies and tetanus. In rabies, although the whole nervous system is charged with the poison, the medulla oblongata, as shown by the symptoms and the microscopical evidences of degeneration of the neurons in that region, is especially affected. In tetanus the characteristic bacilli are only found in the wound. They must, therefore, be comparatively few in number, but they elaborate a virulent poison which affects particular groups of neurons. The fact that lock-jaw nearly always occurs first shows that the poison selects the motor nucleus of the fifth nerve, but it is remarkable that experiment has shown that the tetanus toxin, if mixed with an emulsion of nervous matter before injection into an animal, loses its toxicity, showing its affinity for nervous matter, also a power of absorption of the poison by some chemical substance in the nervous matter. Again, it is probable that some toxic agent absorbed from the alimentary canal having an affinity for the motor neurons, all of which are not equally susceptible to it, is the cause of tetany. It is generally believed that in diphtheria a neurotoxin is produced by the local action of the bacilli, for they do not become freely generalised in the blood and tissues. Whether the poison is a direct product of the bacilli themselves or is an autotoxin created in the body itself by an influence exerted on the living fluids and tissues by a ferment-like product of the bacilli has not been determined, but whateve may be the source of the toxin its effects show a selective affinity for certain nervous structures, as shown by the complex of symptoms which arises. Some people assert that chorea is due to a microbial infection and the result of the action of their toxic products upon certain systems of neurons in the brain, but the evidence is probably as yet insufficient, although the hypothesis is plausible, especially if (as seems now probable) it be shown that rheumatic fever, with which this disease is so frequently associated, is due to that cause. Influenza has, it seems, a specially depressing influence upon the nervous system. The frequency with which this disease is followed by anosmia is doubtless due to the primary seat of infection being the nasal mucous membrane. Many severe neuroses and psychoses date their origin from an attack of influenza.

Finally, I shall refer to a poison which is responsible for a large proportion of the organic nervous diseases which are met with in practice—syphilis, the virus of which may act in two ways. It may produce disease within the nervous system, attacking the supporting and nutrient vascular tissues. It shows a predilection to attack certain structures, especially the inner coat of the cerebral arteries of the base of the brain. Moreover, if it attacks the membranes, it is the base which is especially liable to be affected. There is an explanation for this, for probably the syphilitic organism or contagious particle finds the abundant cerebro-spinal fluid in the subarachnoid space in this situation a favourable region for its multiplication, but why the third nerve should be especially picked out by the poison, and in the great majority of instances on one side alone, has received no adequate explanation. So frequently is this nerve affected in syphilitic disease of the base of the brain that Ricord and Fournier designated paralysis of the third nerve, especially ptosis, "*la signature de la vérole.*" Syphilis, also, is the most important factor in the production of two primary progressive degenerations of the nervous system, one affecting especially the posterior spinal neurons, the central projections of which form the afferent systems of fibres of the posterior columns of the spinal cord—viz., locomotor ataxy—the other affecting especially the frontal and central convolutions of the cerebral hemispheres, general paralysis of the insane. Uhtoff found reflex rigidity of the pupils 492 times among 4000 insane; of these 421 (85·5 per cent.) were paralytic dements.[2] Uhtoff and Möli found the light reflex absent in about half the cases. A striking instance of the selective action of the syphilitic poison is shown in the fact first pointed out by Sir William Gowers, that only in persons affected with acquired or inherited syphilis is the symptom known as the Argyll-Robertson pupil found; indeed, it is sometimes the only symptom. Seeing that this is the most common objective phenomenon in the two diseases mentioned it strengthens the presumption, based on experience, that the syphilitic poison is the essential cause of the two diseases in the majority of instances. Again, in both these diseases a primary progressive degeneration of the optic nerve, in which the vessels have normal appearance—viz., grey atrophy—is frequently met with. I found in 130 consecutive post-mortem examinations made upon general paralytic patients at the Claybury Asylum naked-eye atrophy of the optic nerves in nine cases—nearly 7 per cent. In the Croonian Lectures I stated 10 per cent. as suffering with optic atrophy, but this calculation was based upon cases which I had especially investigated and included a number of juvenile and tabetic cases. The soft sore as a cause of these parasyphilitic affections is well known, and various theories have been put forward to explain why this should be so. To my mind it indicates, in the majority of cases, a mild attack of syphilis. Possibly the poison has been modified by inherited partial immunity, possibly by mixed infection, and both Hitzig and Buzzard have suggested that under such conditions as will produce a

[2] Berliner Klinische Wochenschrift, 1886, Nos. 16 and 17.

soft sore there may be several poisons, one of which is specially injurious to the vitality of certain structures in the nervous system. One finds an analogy in diphtheritic paralysis, for it is a matter of experience that the mild cases are very frequently followed by toxic symptoms affecting the nervous symptoms. In fact, they may be the first evidence of the disease for which the patient is seen by the medical practitioner who ascertains then that the patient (and several others in the house) had suffered from sore-throat. It is remarkable how very slight may be the symptoms of syphilitic poisoning in married women who suffer with miscarriages, premature births, and give birth to syphilitic children. I have investigated 30 cases of juvenile general paralysis. In 80 per cent. of these I found a history or signs of syphilitic infection. Although in 50 per cent. the children showed characteristic signs of congenital syphilis, yet the mothers seldom complained of any illness, nor could I obtain any evidence in the majority of cases that they had had any symptoms of the disease. I am rather inclined to believe that spermatic infection of the ovum from the syphilised father may in some of these cases have taken place, and it is conceivable that as the syphilised fœtus has developed gradually increasing doses of the toxin absorbed by the mother's blood have given her an immunity. Whereas in the adult form of the disease males are much more frequently affected than females, in juvenile general paralysis when the chances of syphilitic infection are equal the two sexes are affected equally.

A Lecture
ON
PLAGUE.

Delivered at the London Hospital on Nov. 22nd, 1900,

BY J. MITFORD ATKINSON, M.B. LOND.,
PRINCIPAL CIVIL MEDICAL OFFICER, HONG-KONG.

LADIES AND GENTLEMEN,—I appear before you this afternoon at the request of the College Board that has done me the honour of inviting me to give you some of my experiences of this now widespread disease, plague. I would incidentally mention that it is 22 years since I was in this theatre as a student. London Hospital men wander far and wide, and it has been my fate to spend 13 years in the Far East, during which time I have practically had the management of three epidemics of this disease. During these outbreaks we have had the services of a staff of nursing sisters, no fewer than nine of whom hailed from the London Hospital. I feel it my duty as well as a privilege to pay a tribute in the college attached to this hospital to the noble services rendered by these ladies, in the performance of whose duties two unfortunately lost their lives.

I have been requested to speak to you on the diagnosis of plague and the measures necessary to prevent its extension. Plague may be defined as an acute infectious febrile disease caused by the introduction into the system of a specific bacillus. In order to diagnose the disease a knowledge of the symptoms and post-mortem appearances is necessary.

SYMPTOMS.

The disease commences suddenly, without prodroma, with a rigor, followed quickly by great prostration, fever, and marked pain at the place where the bubo subsequently appears. After the onset there are headache, great thirst, vomiting, diarrhœa, marked weakness, and, as a rule, intense mental depression. The skin is hot and dry and occasionally jaundiced. The facies is characteristic. The countenance is drawn, the conjunctivæ are injected, and the eyes are sunken. The patient presents a dull, heavy, stupefied look. Sometimes this is replaced by an expression of terror. The tongue is swollen, red, and coated with a greyish white fur. Occasionally the disease is ushered in with violent delirium, the patient being sometimes quite maniacal. At other times the patients are quiet and indifferent to their surroundings owing to a deadening of the mental faculties. Then appear the buboes or enlarged lymphatic glands, to which character the name "bubonic plague" is due. These are the most constant and characteristic signs of plague and they appear at any time in the first five days. The fever is generally high—from 103° to 105° F.—at the onset, lasting from six to 10 days and reaching its acme from the third to the fifth day. Gradually then it falls to the normal. After the first stage there is often a secondary rise due to suppuration. Occasionally we meet with petechiæ or pustular eruptions and carbuncular affections of the skin. These latter begin with ecchymoses, which increase in size and become covered with vesicles, the surrounding skin being swollen and brawny, due to the effusion of inflammatory serum, a central slough often forms which separates, leaving a gangrenous ulcer.

Buboes.—With reference to the buboes or glandular swellings. in 73 per cent. of the cases these appear varying from the size of a pigeon's egg to that of one's fist. In the remaining 27 per cent. the glandular swellings are much smaller, varying from the size of a pea to that of a bean. These smaller lesions occur most frequently towards the end of an epidemic when the symptoms generally are milder. These buboes are accompanied by a painful peri-glandular swelling which is so painful that on the least pressure the patient winces and cries out. The most frequent sites of the buboes are the groin, the axilla, the neck, and the submaxillary region. The relative frequency is as follows: in 60 per cent. they occur in the groin, in 16 per cent. in the axilla, in 15 per cent. in the neck, in 1·5 per cent. in the submaxillary region, and in exceptional cases they also appear in the elbow and popliteal space. In the groin the femoral glands are those most frequently affected. The swelling is rapid and accompanied by so much pain that the patient lies with his thigh flexed and abducted, there is inflammation of the surrounding peri-glandular connective tissue, the skin over the swelling is red and œdematous, very often a bleb forms on the surface, and in 90 per cent. of the cases the bubo suppurates. In addition to these changes in the external glands the internal lymphatic glands are frequently affected, more especially the mesenteric.

To particularise, one may say in regard to the alimentary tract that the lips are dry, the tongue at the onset is swollen and red and coated with a greyish-white fur; usually on the second or third day it has become dry and brown. This brown appearance, especially amongst the Chinese, is very characteristic. The mucous membrane of the pharynx is red and the tonsils are often congested. The appetite is diminished and there are frequent vomiting and intense thirst. Diarrhœa is common at the onset as well as in the later stages; during the fever constipation is the rule.

Respiratory tract.—As a rule there are no symptoms pointing to this tract, but there is occasionally a painful dry cough with signs of dry pleurisy. I am referring to the ordinary bubonic type of the disease.

Cardiac.—In severe cases there is evidence of implication of the heart muscle; the first sound is prolonged, the pulse is rapid and soon becomes soft and compressible, and as the end approaches it is very irregular.

Urinary system.—The secretion of the urine is frequently diminished or altogether suppressed at the onset. In 95 per cent. of the cases in the epidemic in 1896 we found albumin to be present at the commencement of the disease, but this disappears with the decline of the fever.

Nervous symptoms.—These are very marked and consist of deafness, distressing sleeplessness, muscular twitchings, and either delirium or apathic listlessness merging into coma. Pregnant women in many cases abort. Convalescence in favourable cases commences with the decline of the fever at the end of the second week, but it is always long and very often much delayed by suppuration.

Mortality.—There is no disease with such a high mortality. Amongst the Chinese not treated in the hospital the mortality was 90 per cent. Amongst those treated in the hospital it varied in different epidemics from 73 to 88 per cent. Of the Europeans attacked the mortality is much less, averaging from 40 to 50 per cent. During the height of an epidemic the cases are speedily fatal, death often taking place from quite unexpected collapse. At the end of an epidemic the cases are much milder in degree, so that we find the mortality of 90 per cent. at the beginning reduced to 45 per cent. at the close.

POST-MORTEM APPEARANCES.

To diagnose the disease it is necessary, as I have stated, to

have a knowledge of the post-mortem appearances, as the first case may be met with in the cadaver. There is no marked emaciation unless death occurs late in the disease, or from some secondary cause such as long-continued suppuration. Rigor mortis is not well marked. The expression of the countenance is usually calm. On the skin there are petechiæ occasionally found and carbuncular swellings; these show hæmorrhages and infiltration into the subcutaneous tissue. With regard to the brain the cerebral membranes are always congested and œdematous and in most cases clouded; there are small ecchymoses here and there. In the brain substance there is no marked change. As to the chest, in the pleura are small hæmorrhages, with some moderate effusion into the pleural cavities; the mediastinal glands are sometimes enlarged and the lungs are congested and very œdematous, the lower lobes especially so. There is occasionally pneumonic infiltration. The bronchial glands are sometimes enlarged. The pericardial area presents punctiform ecchymoses, the right side of the heart is generally distended with blood, and the heart muscle is pale and flabby, the parenchyma being clouded or in a state of fatty degeneration. As to the abdomen, the omentum and peritoneum present small or large extravasations of blood; these are sometimes very extensive. The mesenteric and retro-peritoneal glands are in nearly all cases enlarged and they present a bluish-red appearance. Occasionally, in severe cases, extensive hæmorrhages can be traced from the crural canal along the lymphatics of the pelvis to the perirenal connective tissue. The spleen is enlarged always to twice or even four times its usual size; it is soft and hyperæmic. The liver also is enlarged; there may be extravasations of blood under its capsule, the parenchyma is clouded, and in those cases in which there has been jaundice the organ is of a greyish-yellow colour. The stomach is often contracted; the mucous membrane is hyperæmic and is thickly coated with mucus and studded with small or large hæmorrhages. The intestines present the same appearances; in addition, the solitary glands are hyperæmic and Peyer's patches are enlarged and occasionally present hæmorrhages. The kidneys are enlarged and congested, with small ecchymoses under the capsule. Small hæmorrhages are found in the mucous membrane of the pelvis and coagula may be seen plugging the calices. The urinary bladder presents punctiform hæmorrhages in the mucous membrane and the urine occasionally contains blood. With regard to the glands, in the external lymphatics or buboes the changes are much more marked than they are in the internal lymphatics. The buboes are swollen lymphatic glands with the surrounding connective tissue œdematous and infiltrated with blood. The glands are red or bluish-red and are frequently studded with purulent foci; they often contain hæmorrhagic extravasations. In severe cases the glands are matted together to form one huge boggy mass which may extend up the crural canal to the pelvis. In severe cases the iliac and lumbar glands have been affected, so that there may be a chain of enlarged glands extending up to the diaphragm, and hæmorrhages into and around these glands are frequently found.

To sum up, the post-mortem changes met with in this disease are as follows: characteristic inflammatory swellings of the external and internal lymphatic glands, especially of the mesenteric glands, accompanied by enlargement of the spleen, by inflammatory changes in the structure of the liver, kidneys, and heart, by inflammation of the cerebral membranes, and by the production of diffuse small punctiform hæmorrhages.

VARIETIES OF PLAGUE.

The varieties of the disease are three: the bubonic, the pneumonic, and the gastro-intestinal.

1. *Bubonic.*—With regard to this variety, it is the one which I have been describing. 70 per cent. of the cases come under this heading. Infection occurs through the skin.

2. *Pneumonic.*—Fatal as is the bubonic variety, the pneumonic is still more so; indeed, nearly all who are attacked by it die. It is induced in animals by applying the bacilli or the sputum of a pneumonic case to the mucous membrane of the nostrils of, say, guinea-pigs, by means of a brush. The sputum of patients attacked by this variety presents almost a pure culture of plague bacilli. Infection occurs by means of the air-passages, and it was from this form that the two sisters in the Government Civil Hospital at Hong-Kong died in the epidemic of 1898. The onset is marked by a rigor, attended by cough and some dyspnœa with slight fever. The temperature soon rises to 103° F. or higher, and in a few hours the patient commences to spit up a quantity of thin blood-stained sputum. The dyspnœa rapidly becomes more marked, there is much cardiac depression, the pulse is rapid and compressible, and there are extreme restlessness, want of sleep, and early delirium; the auscultatory signs are those of catarrhal pneumonia. The disease in this form runs a very rapid course, and is almost invariably fatal within three days.

3. *Gastro-intestinal.*—This variety, like the pneumonic, has no external buboes and the cases are, as a rule, rapidly fatal. Post mortem the changes already described in the mesenteric and retro-peritoneal glands are the most constant; the solitary glands are also enlarged and inflamed and the mucous membrane of the intestines is thickly coated with mucus and studded with small hæmorrhages. In 21 fatal cases of this variety in the epidemic of 1896 plague bacilli were found in the fæces.

BACTERIOLOGY.

It was at Hong-Kong in 1894 that Kitasato and Yersin discovered the bacillus in the buboes and organs of those who had died from the disease and also in the blood of patients who were suffering from the disease. That this bacillus is the cause of the disease is now universally held, the reasons being: (1) the presence of the bacillus in the blood and organs of a person suffering from, or who has died from, the disease; (2) that if a culture of the bacillus obtained from one suffering from the disease be inoculated into a susceptible animal this animal contracts the disease and dies; (3) the bacillus can be obtained from the spleen and other organs of the infected animal; and lastly, (4) the bacillus thus obtained will infect other susceptible animals. This distinctive micro-organism is found in fresh bodies in the spleen and buboes in great numbers, in smaller numbers in the affected lymphatic glands, in the heart, lungs, liver, and kidneys, in the walls of the stomach, in the intestines, and in the blood; in the last-named it is also found in the interior of the blood corpuscles. It is likewise to be detected in the fæces, in the urine, in the vomit, and in the saliva. The bacillus is a short thick rod with rounded ends. On an average it is about one millimetre in length and 0·3 μ in breadth. It is stained by basic aniline dyes, the ends of the bacillus taking the stain more deeply than the centre, thus presenting a bipolar appearance. It is not stained by Gram's method. Examined in media kept at 37° C., which is that at which it thrives best, it is motile. Spore formation has not been observed. In some specimens the appearance of a capsule can be made out. To find the bacillus, a small quantity of blood is obtained by puncturing the finger or lobe of the ear, after carefully washing the skin with soap and water and afterwards with a solution of corrosive sublimate. The blood is then spread on glass slides and dried and stained with some aniline dye, carbol fuchsin by preference. Blood obtained by puncturing the buboes or glandular swellings nearly always contains the bacilli in large numbers.

In 1896, out of 273 cases treated in the hospital, in 221 the presence of the bacilli in small numbers was found in the blood microscopically. As a rule only four or five in any one field of the microscope are found. If the bacilli are free and numerous the case is a serious one. If the bacilli are not found microscopically a more exact opinion is obtained by culture experiments on animals. The most favourable culture medium for this growth in Hong-Kong was found by Wilson to be a 2 per cent. alkaline solution of peptonised bouillon containing 1 per cent. of gelatin. After injection the bouillon remains clear and transparent; the bacilli grow on the surface in the form of a slight whitish clot. The fluid remains clear if undisturbed, but the least movement causes the growth to sink to the bottom of the tube, or for a time the fluid appears cloudy. The urine or the blood may also be examined on agar plates. If the bacilli are present small round greyish-white colonies appear within 24 hours. To make the diagnosis still more precise inoculations of the blood into a susceptible animal, such as the rat, the mouse, the guinea-pig, the rabbit, the pig, or the monkey should be made. The mouse or the guinea-pig is the animal which is most suitable. To communicate the disease to either it is only necessary to prick the thigh with a needle which has been dipped into the culture. The animal refuses food, it staggers, the respirations become hurried, and it dies in from 36 to 48 hours. It

is essential to use a recent culture, otherwise the virulence is lowered. The characteristic post-mortem changes are found in the animal—e.g., at the site of inoculation there is inflammatory œdema, the lymphatic glands are enlarged, the spleen is enlarged and congested, and plague bacilli can be obtained from the spleen, the liver, and the glands.

Plague bacilli are also present in profusion in the sputum of pneumonic patients. In examining the pneumonic sputum advantage is taken of the fact that plague bacilli grow at a much lower temperature than normal microbes. In order to examine sputum for the presence of these bacilli the sputum is first diluted with a small quantity of boiled water; several tubes of bouillon are fertilised with this diluted sputum and are exposed to a temperature not higher than 23° C. At this temperature the pneumococci and streptococci will not grow. The plague bacilli will develop and in two or three days plague colonies will be seen. In order to obtain cultures in a pure state fresh tubes of bouillon should be inoculated. The introduction of pure cultures into the stomach, either by mixing them with food or by giving them with the stomach-tube, is always fatal to rats, guinea-pigs, and rabbits. and the same result occurs if fragments of the organs of animals dead from the disease are used. The post-mortem changes in the mesenteric glands and intestinal follicles are more marked in these cases than they are in the cases of those animals which have been killed by subcutaneous injection. also the external glands are much less swollen. Wilson found at Hong-Kong that guinea-pigs and monkeys fed with pure cultures died from the disease. A pig fed with the spleen of a man who had died from plague succumbed to this disease in three weeks. It is found then by microscopical and bacteriological examination that plague is a disease in which the blood, the organs, the saliva, the urine, and the fæces of those affected with, or who have died from, it contain a specific bacillus, pure cultures of which inoculated into various animals produce in them the same disease. Hence its infectivity, a point which I cannot too strongly impress upon you. Medical men recognise this, but there is a tendency on the part of students to dwell more on the changes in the organs and on the pathognomonic symptoms of a disease. Bacilli have been demonstrated in the saliva and fæces of patients five days after the first onset of the fever; in blood obtained by puncturing the connective tissue of the bubonic swellings and in urine plague bacilli have also been detected from four to six weeks after the onset of the disease. Mice, guinea-pigs, and rabbits when inoculated by cultures attenuated either by cultivation through several generations in artificial media or by heat are gradually rendered immune against inoculation with virulent cultures; from this arises the treatment by antitoxic and preventive serums. Serial inoculation diminishes or destroys the virulence of the bacillus; this may account for the spontaneous subsidence of the disease, also for the smaller death-rate at the end of an epidemic.

DIFFERENTIAL DIAGNOSIS.

The diseases for which plague may be mistaken are typhoid fever, typhus fever, and splenic fever, and in the pneumonic variety it may at its onset be mistaken for influenza. It is distinguished from typhoid fever by its sudden onset, by the absence of the rash and the abdominal symptoms, and in a few days by the appearance of the bubo. Typhus fever has a longer fever stage—viz., 14 days. The difficulties chiefly occur in the severe cases without buboes and in the mild cases with slightly enlarged glands which simulate adenitis, the so-called pestis minor, or pestis ambulans; in all cases, however, the diagnosis can be established by finding the characteristic bacillus.

METHODS TO BE USED TO PREVENT EXTENSION OF THE DISEASE.

In order to prevent the extension of plague we must know how the bacillus is conveyed. Plague bacilli exposed for four hours to sunlight at a temperature of 108° F. no longer grow on bouillon. Similarly exposure for four and a half days to sunlight at a temperature of from 84° to 88° F. (the ordinary temperature at Hong-Kong in the summer) produces the same result. In the exsiccator the bacillus succumbs in three hours. From these facts, and because it has never been found in the air, it is most improbable that plague is an air-borne disease. It is conveyed by men suffering from the disease, by clothing contaminated by urine, fæces, or expectoration of patients suffering from it, and by animals such as mice, rats, and pigs coming from infected districts.

The channels of infection are (1) the skin, (2) the respiratory tract, and (3) the gastro-intestinal canal. The skin is by far the most common source of infection by means of wounds, abrasions. or insect bites. Yersin and other observers have confirmed the fact that it is communicated by fleas. In the respiratory tract infection occurs by the discharge from the nose or mouth. Experiments have proved that guinea-pigs may be infected by simply daubing the nostrils with the sputum from a case of pneumonic plague. With regard to the gastro-intestinal tract, although this is not the usual way of infection, to prove that it may occasionally occur I would call attention to Wilson's experiments in feeding pigs with plague bacilli. It is also just possible that in the epidemic of 1896 the disease may have been introduced to Hong-Kong by infected pigs. In August of that year a number of pigs died on a steamship coming from Pakhoi to Hong-Kong; plague was then prevalent at Pakhoi. Wilson examined some of these animals and found that the post-mortem appearances were similar to those met with in plague. A bacillus was obtained from the organs of these pigs which was not to be distinguished from the bacillus of man; the injection of cultures of this bacillus in animals produced the same pathological changes met with in plague. In 1899 Cheung Chau, a small island some 15 miles from Hong-Kong with 1000 inhabitants, was almost decimated by plague. On inquiry I found that preceding the outbreak there had occurred an epidemic amongst the pigs on the island and during that time diseased pork was selling at about one-third the usual price. The Chinese eat sun-dried pork—that is, pork which has not been cooked. Wilson found that plague bacilli remained active for three days in pork which had been boiled if it had not undergone decomposition. It might be said that the human gastric juice would kill the bacillus, but that has not been proved. Wilson found that the bacillus lived for three days in a one-half per cent. solution of hydrochloric acid. Another point in favour of food infection is that in infected houses frequently members of only one family are affected. As with cholera so with plague, the water from an infected area must be regarded as dangerous, seeing that this may be contaminated with plague bacilli by means of the urine and fæces from patients suffering from this disease.

Having dealt with the methods by which it is conveyed we are better able to state the measures required to combat the disease. I will divide these into two: first, public hygiene; and second, the precautions necessary for the individual, or private hygiene.

HYGIENIC REGULATIONS.

Public hygiene.—The importation of the bacillus must be prevented as far as possible. This is the duty of the port medical officers of health, supervised by other medical officers and the inspector of the Local Government Board. If a person arrives from an infected port suffering from plague, or from an illness suspected to be plague, he must be isolated and his dejecta must be rendered harmless. The cabin occupied by the patient, and the ship generally, must be disinfected. All fomites belonging to the patient should be destroyed. All those who have been in contact with the infected person must be kept under medical supervision for 10 days as this is supposed to be the incubation period. As with cholera so with plague, all water from an infected port should be regarded as dangerous. Should the disease occur on shore those suffering from it should be isolated, the dejecta should be burnt, and the house and the articles belonging to the patient should be thoroughly disinfected. All persons who have been in contact with the patient must be segregated under medical supervision for 10 days. The hygienic condition of privies, drains, &c., must be attended to, and a house-to-house visitation of the infected neighbourhood should be made. Meat from infected ports should be inspected. Rats should be destroyed, as it seems that they have played an important part in the production of some epidemics. In China dead infected rats are frequently precursors of outbreaks and are found lying dead in the streets. Patients who have died from the disease should preferably be cremated.

Private hygiene.—During the prevalence of the disease those in attendance on the sick should maintain perfect cleanliness of the person; the hands should be frequently washed and watch should be kept for the slightest abrasions or wounds of the skin. All attendants on the sick should not eat in a sick room and should be most careful to disinfect their hands and face. All food should be well cooked and the dishes should be cleansed with boiled water. Houses

known to contain, or suspected of containing, cases of plague should not be visited unless at the call of duty.

I have necessarily only dealt briefly with the measures to be taken in dealing with this disease. In conclusion, I will give you briefly the procedure adopted in Hong-Kong in dealing with the outbreaks of this disease.

MEASURES ADOPTED IN HONG-KONG.

House-to-house visitation.—The disease is notifiable in Hong-Kong and has been so since 1895, but as this notification is universally evaded by the Chinese, immediately on the receipt of information that the disease has reappeared a house-to-house visitation of the infected districts is made. The sanitary authority has the power to institute such visits in any districts in which the disease may prevail. It must define the limits of such districts and this house-to-house visitation is effected by officers of the board assisted by the police. The removal of the sick and dead is conducted in ambulances provided for the purpose and kept at the hospitals and police-stations. The dead bodies are taken to the public mortuary and there they are examined by a medical officer; those who have died from plague are buried in the cemetery set apart for that purpose, the coffin being packed with chloride of lime or carbolised sawdust.

Segregation of contacts.—At the outset arrangements are made for the isolation of all those who have been in immediate contact with cases of the disease in the infected houses. It will be remembered that in the recent outbreak in Glasgow this measure was employed. When the daily number of cases increased greatly the continuance of this system was found to be impracticable, and the following method was adopted in Hong-Kong. Sheds were erected in various parts of the city to which occupants of the houses were taken whilst their clothing and effects were being disinfected, after which the persons were allowed to return to their own homes.

Isolation hospitals are provided. In my opinion these are better if made of wood—temporary structures which can be destroyed.

Disinfection of infected premises.—This consists in spraying the walls with a solution of corrosive sublimate (1 in 1000) or fumigating with free chlorine gas. The floors and furniture are then scrubbed with a solution of Jeyes fluid, and the walls are limewashed.

Latrines.—Special attention is paid to the disinfection of all public latrines by means of chloride of lime.

Sewers.—Extra flushings of the sewers are carried out by increasing the frequency of the discharges of the flushing tanks which are placed at the heads of all the main sewers.

Destructor.—The night soil at the isolation hospitals and all dressings of the patients are burnt in the hospital compound after having been mixed with sawdust.

Antitoxin.—A supply of Haffkine's antitoxic serum is kept and supplied free of cost.

Rats.—A reward is given for each rat brought to the sanitary authority; in this way 25,000 rats were collected and destroyed in 1900 from January to July.

Anyone acquainted with the conditions of overcrowding, filth, and ignorance that exist in China cannot fail to see that it will be years before plague can be stamped out of that country. To show the overcrowding that exists in some parts of Hong-Kong I may mention that in one health district in that city there are 975 people to the acre. In England, of course, these conditions do not exist, but still there are many localities where, if this bacillus obtained a footing, it would grow and spread. Therefore one must be on the look out in order that if the disease should be introduced it may, by active measures, be checked at the onset.

[Dr. Atkinson then showed lantern views of the plague bacillus and of the plague operations in Hong-Kong, of search parties, and of native plague hospitals, &c. Dr. Bulloch gave a short account of the plague bacillus and the dangers to be feared from inexpert tampering with buboes, and especially the danger arising from the pneumonic form.]

ENLARGEMENT OF BROCKWELL PARK.—For this praiseworthy scheme public companies and private donors have contributed £63 350 of the £66,700 required for the proposed addition of 43 acres to this park at Herne Hill and the necessary legal confirmation of the recent provisional contract for the purchase has been obtained. The acquisition of this additional land will provide for a greatly felt want.

A SUGGESTED METHOD OF PREVENTING WATER-BORNE ENTERIC FEVER AMONGST ARMIES IN THE FIELD.[1]

BY LOUIS C. PARKES, M.D. LOND., D.P.H.,
MEDICAL OFFICER OF HEALTH OF CHELSEA;
AND
SAMUEL RIDEAL, D.SC., F.I.C.

EVERYONE is aware that our troops in the South African campaign have suffered very severely from enteric fever—notably in the Bloemfontein outbreak following Lord Roberts's march from Paardeberg. Numerous questions arise in connexion with this outbreak and with the very general prevalence of enteric fever during the campaign which we may hope to see answered when the whole conduct of the war has been under review. In the meantime these questions may be briefly summarised as follows:—1. Has the number of cases of enteric fever proportional to troops employed exceeded that characterising other campaigns in similar climates with similar disadvantageous sanitary surroundings? 2. Was the likelihood of enteric fever becoming epidemic amongst the troops foreseen by the military authorities? 3. Were the best practicable and available means taken to safeguard the army both in stationary camps and when on the march? The answers to these questions will be awaited with immense interest not only by the medical profession but by nearly every person of intelligence who has followed the various incidents of the war.

There can hardly be any doubt on the point as to whether the infection of enteric fever was introduced into South Africa by British troops or was conveyed to the latter from pre-existing sources in the country which was the seat of warlike operations. Enteric fever is endemic in South Africa and prevails in many parts of the country every summer season, whereas the troops leaving England, and probably those also from India and the British colonies, were subjected to medical inspection before embarkation and were no doubt very free from the disease on arrival at the Cape. It is evident, therefore, that the British Imperial forces must have become infected in South Africa by local conditions and did not carry the disease with them from their homes. Again, it seems highly probable from what is known of the mode of spread of enteric fever that the first cases amongst the troops arose from the consumption of water infected with the enteric virus, derived either from the civil population with whom the troops were brought into contact or more probably from the Boer combatants, amongst whom it is generally supposed the disease was present from their first taking the field. Once established amongst our own forces by means of infected water it is quite likely that the subsequent spread was largely due to personal infection from the necessarily prevailing conditions of camp and veldt life—that is to say, common latrines, uncovered and undisinfected excreta, flies carrying contagion from the excreta to the food, dust-storms depositing infective material on food and drink, absence of isolation of the sick, and the want of proper hospital appliances.

Inasmuch as troops on the march are always very careful to choose camping grounds which have not been previously in use unless strategical reasons render such a course necessary, whereas they are often dependent for their water-supply on sources which have been already defiled, either by the enemy or by advance columns of their own side, the assumption would appear to be warranted that if it were possible to render all water used in drinking by the troops innocuous there would be no general development of enteric fever on a large scale sufficient to cripple an army such as has been the case during the present campaign.

We await information as to what has been the practical experience with the South African army of the attempts made to sterilise water for the use of troops, either by boiling or by filtration. Even now, however, it is almost safe to assume that such methods can only have a practical application at stationary camps, and are impossible of

[1] A paper read before the Epidemiological Society on Jan. 18th, 1901.

attainment during the rapid marches and swift changes of position that war conducted on modern methods necessitates. The feature of the wars of the future will probably be, as the result of recent experience, the employment of highly mobile forces. Troops, both foot and mounted, will be expected to move with great rapidity and with very short intervals for rest; transport will be reduced to a minimum; and the filtration or boiling of water for troops on the march will be impracticable. We have not yet heard the full medical details of the march of Lord Roberts's army from the Modder to Bloemfontein, but it seems certain that the infantry outmarched both their regimental and brigade transport and were dependent for their drinking water upon the polluted streams or dams which they crossed and which in many instances had been already grossly fouled by the retreating enemy. Even if filters or boiling apparatus can be made to accompany a rapidly moving column it is very doubtful if men parched by long marches performed under a fiery sun and in clouds of dust can be restrained from slaking their thirst as soon as they arrive at water. It is more than can be expected from human nature under such circumstances to await the tedious delivery of the sterilising filter or the cooling of the water that has been heated to a boiling temperature. The agonies of thirst are intense and at the time far outweigh any such considerations as those of prospective illness from the consumption of a germ-tainted water.

Failing, therefore, the sterilisation of water by boiling or filtration, is there any substance which can be added to water which will destroy the virulence or inhibit the growth of the bacillus typhosus whilst not rendering the water unpalatable or injurious to the health of the consumer? It is evident that the ordinary poisonous, or even non-poisonous, disinfectants are inadmissible for this purpose, as if added to the water in quantity sufficient to exert a germicidal action they would undoubtedly prove harmful to the consumer, if not at first at any rate after repeated doses.

There are other substances, however, which might be expected to prove beneficial as regards their effect upon bacillus typhosus whilst not harmful to the consumer. Such are the dilute mineral acids—dilute sulphuric acid, B.P., and dilute nitro-hydrochloric acid, B.P.—and the organic acids, citric and tartaric, which are largely used in the manufacture of lemonade. Other substances with which we have experimented are acid bisulphate of soda, acid phosphate of soda, and sulpho-vinate of soda. All of these are bodies of which the human system is tolerant, whilst in the proportions which we have found to be required (after contact of from 15 to 30 minutes) to inhibit the growth and activity of bacillus typhosus they are quite palatable, imparting a sub-acid flavouring which is agreeable to the taste and would materially aid in quenching thirst.

As regards previous investigation of this subject, sulphuric acid has been shown by A. Stutzer to be fatal to cholera bacilli in 15 minutes when used in the proportion of 5 parts to 100,000 of water (0·05 per cent. solution). Hydrochloric and nitric acid are probably equally efficacious, but it does not appear that any sufficiently detailed experiments have been made on the destructibility of the organism of enteric fever. Dr. Christmas in 1892 showed that citric acid, although fatal to the cholera bacillus when used in the proportion of 8 parts in 10,000 parts, did not destroy the bacillus of typhoid fever in a less strength than 1 in 1000. Reinsch[2] states that 0·028 per cent. of tartaric acid in water "began to diminish the bacteria and 0·2 per cent. killed them." Tartaric acid has also been employed in filters and its use has recently been suggested in Italy for sterilising salads before consumption.

Schumberg's[3] bromine process for purifying water is specially advocated for army purposes, for sterilising water in the tropics, for use on ship-board, and in the case of waters derived from suspected or infected barbours. It consists in adding 0·06 grain of free bromine dissolved in potassium bromide solution for every litre of water. The excess of bromine is removed by adding an equivalent quantity of ammonia which renders the water palatable. Pfuhl states that the small quantity of bromide present is entirely devoid of the possibility of injury to health and that the taste can scarcely be distinguished from that of the water before treatment. In July, 1897, Braithwaite suggested the use of a mixture of bromide and bromate, added to the water in the form of a tabloid, to be followed by a tabloid of acid sulphate of soda or potash. A similar mixture is sold under the name of "bromidine." The quantity of bromine recommended was that obtained from two grains of bromide, or about one grain per quart, which gives only about one part in 17,500 of water. This quantity is much smaller than the authorities recommend for sterilisation. About one part in 2000 seems to be a safe quantity to use, or nine times the amount suggested above; and this would render the quantity of bromide finally formed and remaining in the water rather too high for dietetic use.

EXPERIMENT I.—*750 Cubic Centimetres of Tap Water Infected with One Drop of a 24 Hours' Broth Culture at 37° C. of Bacillus Typhosus (J. 1).*

Agar plate cultures made with 1 cubic centimetre of mixture, and colonies counted after 48 hours' incubation at 37° C.	Results obtained after contact of infected water with acid solution for periods of—			
	5 mins.	15 mins.	45 mins.	24 hours.
Sodium bisulphate.				
1 gramme per pint of infected water.	Bacillus typhosus killed.	Sterile.	—	—
½ gramme per pint of infected water.	—	Marked reduction.	Bacillus typhosus killed.	—
¼ gramme per pint of infected water.	—	—	No reduction.	—
Tartaric acid.				
20 grains per pint of infected water.	—	Sterile.	—	—
10 grains per pint of infected water (A).	Marked reduction.	Three colonies.	—	—
10 grains per pint of infected water (B).	—	Bacillus typhosus killed.	Sterile.	—
5 grains per pint of infected water.	—	—	No reduction.	One colony.
Citric acid.				
20 grains per pint of infected water.	—	Sterile	—	—
10 grains per pint of infected water.	Slight reduction.	30 colonies.	—	—
5 grains per pint of infected water.	—	—	—	No reduction.
Nitro-hydrochloric acid, B.P. dilute.				
20 minims per pint of infected water.*	—	Sterile.	—	—
5 minims per pint of infected water.	—	—	—	No reduction.
Sulphuric acid, B.P. dilute.				
20 minims per pint of infected water.	—	Reduction.	Bacillus typhosus killed.	—
5 minims per pint of infected water.	—	—	—	No reduction.

* The acidity of this solution is equal to 4·8 cubic centimetres $N_{10}NaOH$ per litre and the corresponding H_2SO_4 solution 5·8.

The tabular statement of Experiment I. shows that the substances therein given, when used in sufficient strength and allowed to remain for a sufficient time in contact with the infected water, are capable of preventing any further growth of bacillus typhosus when some of the infected water is agar plated. In the case of tartaric, citric, and nitro-hydrochloric acids it does not appear that anything less than the maximum British Pharmacopœia dose per pint of water is efficient to sterilise if the contact is not to last longer than 15 minutes. Half the maximum dose (10 grains) per pint is inefficient in the case of citric and tartaric acids after 15 minutes' contact, whilst the minimum dose (five grains) per pint of citric acid has no effect after 24 hours' contact; and in the case of tartaric acid the minimum dose did not completely sterilise after the same period. Of the two tartaric acid appears to be the mos

potent in its destructive action upon bacillus typhosus. The pint has been taken as a standard, as this is the quantity of water which a man might be expected to drink off at once. One gramme to the pint is equivalent to 1 in 568.

As regards the dilute acids, nitro-hydrochloric and sulphuric, the former appears to be more efficient than the latter; but no further experiments were made with them, as it was considered essential that the substance to be carried by individual soldiers in the field should be a solid, which could be made up into small tabloids, and not a liquid, which would have to be carried in a bottle and be measured out with some exactitude when required for the purpose of sterilising the water to be used for drinking.

Acid sodium bisulphate is not a British Pharmacopœia medicinal substance. It probably has no purgative effect, as the astringent properties of its free sulphuric acid would tend to counteract any laxative action of the sodium sulphate. The minimum purgative dose of sodium sulphate is a quarter of an ounce, and as we only suggest the use of 15½ grains of the bisulphate to every pint of water a man would have to drink seven pints of water before a quarter of an ounce of a salt, not known to be purgative, would be taken. Even if this quantity of water was drunk in a day there is no evidence that a quarter of an ounce of the bisulphate would exert any harmful effect. There is evidence from the table in Experiment I. that the bacillus typhosus is killed by only five minutes' contact with sodium bisulphate in the proportion of one gramme (15½ grains) per pint of infected water; but in our opinion it is better that contact should be made for fifteen minutes in order that sterility may be insured.

As regards acidity the same amount of acid, as measured by decinormal soda solution, appears to be required to produce a similar result in nitro-hydrochloric acid (dilute B.P.) and sulphuric acid (dilute B.P.), sodium bisulphate in the proportion of one gramme to the pint contains about two and a half times the acidity of 20 minims of sulphuric acid (dilute B.P.). If anything, the nitro-hydrochloric acid appears to be most efficient *quâ* acidity; and this is intelligible when it is recollected that there is likely to be a small quantity of free chlorine in this acid, chlorine having very marked disinfectant properties. The citric and tartaric acids to be efficient must contain at least three times the amount of acid as measured by decinormal soda solution that is sufficient for nitro-hydrochloric and sulphuric acids.

Experimental trials were also made with acid sodium phosphate and with sodium sulphovinate, but they were found to be inefficient.

In order to show that the presence of one cubic centimetre of the acid solution in the agar does not affect the capacity for growth of the bacillus typhosus an experiment was made by adding some of the blank infected water directly to agar tubes containing one cubic centimetre of the acid solution. After 24 hours' incubation at 37° C. the plates showed very numerous colonies in every instance.

EXPERIMENT II.—*800 Cubic Centimetres of Boiled Tap Water Infected with Two Drops of a 24 Hours' Broth Culture of Bacillus Typhosus at 37° C.*

Agar plate cultures made with 0·2 cubic centimetre of the mixture.	Results obtained after contact of infected water with acid solution for periods of—	
	5 mins.	15 mins.
Sodium bisulphate, 1 gramme per pint of infected water ...	Six colonies.	Bacillus typhosus killed.
Tartaric acid, 1 gramme per pint of infected water	120 colonies.	50 colonies.

The tap water was boiled and then cooled before infecting in order to kill the few organisms present capable of growth at blood-heat in the agar and so facilitate the subsequent counting of the typhoid colonies.

Experiment II. is confirmatory of Experiment I., but the typhoid bacilli in this experiment were either more numerous or more resistant than in Experiment I., as the results are not quite so good. The water was infected with two pipette drops of the broth culture instead of with one; on the other hand, only one-fifth cubic centimetre was used for plating the agar instead of one cubic centimetre, as in Experiment I. The inferiority of tartaric acid to sodium bisulphate (equal strengths of each being used) is well shown in this table.

EXPERIMENT III.—*100 Cubic Centimetres of Boiled Tap Water Infected with One Cubic Centimetre (approximately 20 Drops) of a 24 Hours' Broth Culture of Bacillus Typhosus at 37° C. Sub-cultures made into Broth Tubes (Incubated for 48 Hours) by Three Platinum Wire Loopfuls after Contact of Infected Water with Acid Solution for Periods of—*

* Growth after 48 hours somewhat inhibited in the sub-culture.

Experiment III. shows that when a water is heavily infected with culture of bacillus typhosus (to the extent of 1 per cent.) the time of contact must be very materially increased to prevent subsequent growth of the bacillus in broth. Sodium bisulphate (one gramme per pint of infected water) is then only effective if contact has been made for 45 minutes. Tartaric and sulphuric acids in similar strengths did not prevent the subsequent growth of the bacillus after 45 minutes' contact.

EXPERIMENT IV.—*500 Cubic Centimetres of Boiled Tap Water Infected with One Drop of a 24 Hours' Broth Culture of Bacillus Typhosus. Four Different Cultures were used, marked respectively J 1, R, B, and M, thus making Four Infected Waters. The one marked J 1 was found to contain 9120 Colonies of Bacillus Typhosus per One Cubic Centimetre.*

* Greatly reduced when compared with the blank (control experiment.)

Experiment IV. was made to ascertain if any variation arose from the use of broth cultures of bacillus typhosus of different origins. The one marked J 1 was used in the preceding experiment. The others, marked R, B, and M, were kindly forwarded to us by Dr. W. G. Savage of Cardiff. The results, on the whole, show but comparatively little divergence, having regard to the fact that the waters were infected with four different cultures of varying degrees of remoteness from their original stocks.

It may be used as an argument against the deductions which we think that we are entitled to draw from our experiments that in broth cultures of bacillus typhosus the organisms are living under artificial conditions, and that waters infected by natural means derive the living virus directly from the fæces or urine of an enteric fever

patient. There would be reason in such a line of argument if it could be shown that the bacilli on emerging from the human body are more resistant to adverse agencies, such as our chemical solutions are, than those which have been cultured and sub-cultured in broth. That this is not generally held to be so is now recognised, for the probabilities are in favour of the view that pathogenic organisms by propagation in artificial media outside the human body tend to become saprophytic, and whilst very probably losing in virulence yet acquire higher resistant powers to agencies affecting their life and growth than they ever possessed when they flourished as parasites in the human body. The two properties of virulence and resistance to external destructive agencies must be clearly differentiated. We think there is every probability that the agency which proves fatal to the sub-cultured bacilli would have an equal, if not greater, effect upon organisms of high virulence immediately derived from the excreta of an enteric fever patient.

EXPERIMENT V.—*(1) 750 Cubic Centimetres of Boiled Tap Water Infected with Three Drops of a 24 Hours' Broth Culture of Bacillus Typhosus (approximately 0·2 of Broth Culture to 1000 of Water—1 Cubic Centimetre yielded 12,000 Colonies). (2) 500 Cubic Centimetres of Boiled Tap Water Infected with Five Drops of a 24 Hours' Broth Culture of Bacillus Typhosus (approximately 0·5 of Broth Culture to 1000 of Water). (3) 400 Cubic Centimetres of Boiled Tap Water Infected with Eight Drops of a 24 Hours' Broth Culture of Bacillus Typhosus (approximately 1·0 of Broth Culture to 1000 of Water—One Cubic Centimetre yielded 52,000 Colonies).*

Agar plate cultures made with 1 cubic centimetre of the mixture.	Results obtained after contact of infected waters (1, 2, 3), with acid solution for periods of—	
	15 mins.	22 mins.
Sodium bisulphate, 1 gramme per pint of infected water ...	Sterile.	—
Three 5-grain tabloids* per pint of infected water	100 cols.	2 cols.

* The tabloid took seven minutes to dissolve. It only contains 73 per cent. of the theoretical amount of acidity a five-grain tabloid of sodium bisulphate should contain, showing that about one-quarter of the tabloid is made with some inert substance. The experiment was made with No. 1 water only.

Experiment V. shows that sodium bisulphate in the proportion of one gramme per pint is effective after 15 minutes' contact, even for waters containing as many as 50,000 colonies of bacillus typhosus per one cubic centimetre. The tabloid of the same substance takes some minutes to dissolve; and as it contains some 27 per cent. of inert matter it is not surprising that the results obtained with it are less successful than those obtained with the pure chemical.

This experiment leads us to the consideration of the dose of the poison or the number of bacilli which must be imbibed in order to induce the disease—a subject on which practically nothing certain is known. On the one hand, waters which were believed on well-founded grounds to have been productive of outbreaks of enteric fever have been bacterioscopically examined—usually several weeks, however, after the period at which they were supposed to be infective—and no typhoid bacilli have been isolated; on the other hand, it is now known that in some 25 per cent. of all cases of enteric fever the urine during the later stages of the disease and during a prolonged convalescence may be teeming with bacillus typhosus, in some cases being actually turbid from the presence of many millions of these organisms per cubic centimetre. It will be easily understood how, if but a small quantity of such urine finds its way into drinking water, such water may become infected with bacilli exceeding in numbers per cubic centimetre any of those which have been artificially manufactured in the laboratory during the course of our research, although from Experiment III. it appears that sodium bisulphate has a considerable effect even when pollution to the extent of 1 per cent. has occurred.

It is reassuring, however, to know that it is only in about 5 per cent. of these cases of infective urine[4] that this liquid is rendered turbid by the presence of the bacilli, so that the condition is only actually present in about 1·25 per cent. of all cases of enteric fever. It is very doubtful also if the bowel excreta at any time contain bacilli at all comparable in numbers with those now known to be occasionally present in the urine of convalescing patients.

On the whole, it would appear as if we might be justified in assuming (1) that water naturally infected with the virus of the disease does not contain so very large a proportion of the bacillus; (2) that this organism is not by any means resistant to acids or other weak disinfectants; and (3) that the use of such simple means as here suggested by us for combating infection has possibly a future before it, more especially under conditions of life where the means of sterilisation by boiling and filtration are not readily available.

As regards the use of sodium bisulphate during a campaign we would recommend its being employed in the form of tabloids—each tabloid to contain five grains of the bisulphate. The tabloids should be made to dissolve quickly in water, and for this purpose the minimum quantity of gum arabic or other adhesive substance should be used in their manufacture. The tabloids should be put up in well-made light metallic boxes, to hold about a quarter of a pound weight—equivalent to about 350 tabloids—enough to sterilise over 100 pints of water at the rate of three per pint. One of these boxes should be carried by every soldier in his haversack. Supposing a soldier to consume five pints a day when on the march, the quarter of a pound tin would suffice for nearly three weeks, at the end of which time he will probably again be in touch with his transport. Instructions should be given by the medical officer to the rank and file as to the use of the tabloids, and more especially as to the desirability of allowing all contaminated water to remain in contact with the dissolved tabloids for at least 15 minutes before being consumed. The soldier of the future, it is now recognised, must have more intelligence and more individual initiative; and this should extend as much to the care of his health when in camp or on the march as to his action on the battlefield. The acid tabloids will be found to render the water much more effective in slaking thirst and there will in consequence be less inclination to drink large quantities of water, a smaller quantity when acidulated sufficing. The tabloids may also be used as thirst lozenges when water is scarce and will, we believe, be found to be useful by promoting the secretion of saliva and so preventing parching of the mouth. We are informed by an officer recently returned from the war that he found the "thirst lozenges" he took out with him from England most useful. There was an immense demand for them by the men of his company, and the men who took them were satisfied with much less water than those who failed to obtain any.

In a country such as South Africa, where the heat of the day is generally very great and water is scarce and often polluted, it seems very desirable that something should be done both to diminish the inevitable sufferings of our soldiers from thirst and to protect them from the ravages of water-borne disease.

NOTES ON ACQUIRED SYPHILIS OF THE NOSE AND PHARYNX.

BY CHARLES A. PARKER, F.R.C.S. EDIN.,
SURGEON TO THE HOSPITAL FOR DISEASES OF THE THROAT, GOLDEN-SQUARE.

THE manifestations of syphilis are very frequently met with in the upper air-passages. If they are promptly recognised and suitably treated they may be classified amongst the curable ills to which mankind is liable. If, on the other hand, either through the patient's carelessness or through faulty diagnosis the disease is allowed to gain the upper hand there is hardly any limit to the amount of damage which may ensue. The following paper on the subject is based upon observations made chiefly at the Hospital for Diseases of the Throat, Golden-square.

In considering this subject I shall lay the most stress on such signs and symptoms as should lead to the prompt recognition of the trouble, for the diagnosis having been established the treatment is much the same in these cases as

it is in syphilis elsewhere. Primary and secondary lesions must be met by the internal administration of mercury in some form, and tertiary lesions must be treated with iodide of potassium. There is, however, one special feature in the treatment of tertiary syphilis of the throat and nose which must be borne in mind, and that is that very often iodide of potassium alone, even in very big doses, is inefficient, whilst the affection will readily yield to iodide of potassium and mercury combined. The best way of administering the mercury in these particular cases is by inunction. This should not be left to the patient, but poor folk should be admitted to the hospital and the well-to-do should obtain the services of a trained nurse. It is often surprising how rapidly improvement will result from this method even in cases where iodide of potassium has been taken for months without any benefit. As an example of this I may mention the case of a girl who came to the hospital with tertiary ulceration of the palate and vault of the pharynx. She was treated with iodide of potassium in doses ranging from 10 grains to 30 grains three times a day and iodoform was applied locally, but in spite of this the disease persisted and spread. The epiglottis was attacked and later the cords, and finally large gummatous deposits occurred below the cords giving rise to dangerous dyspnœa. I admitted the patient into the hospital with the intention of doing tracheotomy, but as she was under the constant supervision of the house surgeon I thought that I would first try the effect of mercurial inunctions. This was done and the necessity for tracheotomy disappeared. This case had been under treatment for about two years, during which time there had constantly been signs of active disease, occurring first in one place and then in another, and healing had never been perfect in any part; but directly mercurial inunction was adopted in addition to the internal administration of iodide of potassium the disease was kept under perfect control. The ulcers healed, the gummatous swellings below the cords disappeared, and the patient made an excellent recovery.

There is one other point to be remembered in the treatment of tertiary syphilis. When there is much stenosis of the larynx iodide of potassium must be given with great caution, for its first effect is often to cause rapid œdema of the laryngeal mucous membrane and so greatly to increase the obstruction. If, therefore, there is much obstruction to start with, iodide of potassium should only be given if the patient is within easy reach of help, for tracheotomy might become urgently necessary.

PRIMARY SYPHILIS IN THE NOSE.

Primary sore.—This is very rare, although there are several cases on record. Its seat is generally on the alæ or just within the vestibule, though cases have been seen where the sore was on the mucous membrane of the meatus. The following case gives a picture of the trouble. A male, aged 50 years, came to the hospital with the complaint that the left nostril was blocked and that there was some blood-stained discharge. On examination the whole of the nose was found to be swollen and œdematous, and within the left ala of the nostril there was a thickened indurated swelling, of about the size of a bean, extending on to the mucous membrane and covered with brownish-red crusts. The tumour was very hard, but it was not very tender or painful. The rest of the respiratory tract was quite normal. There were, however, very marked and hard swelling of the left submaxillary gland and slight enlargement of the occipital glands. Mr. Spencer Watson reports a case which occurred in a nurse in which there was a well-marked tumour just within the nostril causing stenosis and accompanied by swelling of the submaxillary gland of the same side. These symptoms were followed in due course by secondary syphilis. The tumour was caused by picking the nose with an infected finger.

Thus a hard swelling about the alæ or vestibules of the nostrils causing stenosis but comparatively little pain or inconvenience and accompanied by unilateral swelling of the submaxillary glands should arouse a suspicion that the trouble may be primary syphilis. The tumour has always a very hard base and bleeds easily. The disease with which this trouble is most likely to be confounded is sarcoma, especially if the chancre is on the true mucous membrane.

SECONDARY SYPHILIS OF THE NOSE.

The following manifestations of this disease are met with: (1) coryza; (2) mucous patches; (3) rhinitis erythematosa and rhinitis papulosa; and (4) superficial ulceration.

1. *Coryza.*—This is the earliest and commonest manifestation of secondary syphilis in the nose. It is, however, hardly distinguishable from an ordinary catarrh and is often overlooked. In syphilis the rhinitis is of a subacute type and lasts for a long time. The discharge is scanty and sometimes brownish in colour. The mucous membrane, especially that over the inferior turbinated body is dark and purple-coloured in appearance and looks dry. The coryza commences about the time of the appearance of the rash.

2. *Mucous patches.*—There is a great divergence of opinion as to the occurrence of mucous patches in the nose. I have never seen a case, though I have examined for them in cases where there has been a plentiful supply of them in the mouth and throat.

3 *Rhinitis erythematosa and rhinitis papulosa.*—These conditions are said to accompany the roseolar and papular eruptions of the skin respectively. They are undoubtedly seen round the nostrils and in the vestibules, but probably they never extend on to the true mucous membrane.

4. *Superficial ulceration.*—This is said to occur through the breaking down or erosion of mucous patches, and of necessity it must be extremely rare. Superficial ulceration when it does occur is generally an early tertiary symptom, and it will be described under that head.

From the foregoing remarks it may be gathered that secondary syphilis does not attack the nose in any very definite or serious way. The only symptom that one is likely to be called upon to treat is the coryza, which by producing stenosis of the nostril often causes distress and headache. If the coryza itself or any other accompanying symptom leads one to diagnose syphilis, mercury must be given internally, and such simple local remedies as would be employed for ordinary catarrh must be used.

TERTIARY SYPHILIS OF THE NOSE.

This may be met with in any of the following forms:—(1) gummata; (2) superficial ulceration; (3) deep ulceration and necrosis; or (4) scars, adhesions, and deformities.

1. *Gummata.*—In the nose these break down and ulcerate so quickly that they are seldom seen intact; yet it is most important to be able to recognise them, for appropriate treatment administered promptly may save the patient from all the distress of ulceration and necrosis which are sure to follow if the case is left untreated. The subjective symptoms of gummata are few. There may be some snuffling and slight pain, which is often of a deep boring nature and is worse at night, and there is more or less nasal obstruction. Such symptoms as exist are usually unilateral, at all events in the early stages of the trouble. The septum is the part by far the most commonly attacked, though the turbinated bodies, and especially the inferior turbinated body, may be the seat of the gumma. If the inferior turbinated body is attacked its appearance is very like that of ordinary turgescence; a gumma is, however, firmer and more resistant to probing, and it does not collapse on the application of cocaine. Occasionally the gumma is so small and situated so far back that it cannot be seen, and then the character of the pain and the history of syphilis must be relied on for arriving at a diagnosis. The septum may be attacked in one of two ways: either there is a circumscribed gumma, or the whole of it is infiltrated with gummatous material. The latter condition is by far the commoner. The circumscribed gumma is seen as a large prominent rounded mass projecting from the septum and often impinging on the inferior turbinated body, whilst in diffuse gummatous infiltration the septum is seen to be irregularly thickened and swollen. In some parts the swelling is so great as to block the nasal passages, whilst in other places it is a mere thickening of the mucous membrane. In both forms the mucous membrane is smooth and unbroken, but it may be paler than usual owing to its being stretched over the swelling. To the touch the gummata are hard or semi-elastic until they commence to break down, when they become gradually softer. In making a diagnosis spurs and deflections of the septum must, of course, be excluded, but this should not give any trouble upon careful examination of the nose. Then the circumscribed gumma, especially when softening has commenced, must not be mistaken for a chronic abscess. Here, again, the history of the case and a careful examination of the parts should render the diagnosis easy. The trouble, however, most likely to be confounded with gumma is sarcoma, but the latter is softer, it has a definite attachment which is generally high up on the septum, it becomes pedunculated and is then moveable, it

bleeds readily on being touched, and there is usually a history of frequent epistaxis. The gumma is, moreover, essentially an infiltration, whereas the sarcoma is an outgrowth. If there is any doubt iodide of potassium should be given internally, and if this does not determine the diagnosis a piece should be punched out and a microscopic examination should be made.

2. *Superficial ulceration.*—This is not at all common, but it occasionally occurs from three to five years after infection. As before stated, it is thought by some to be a secondary symptom and to be due to the breaking down of mucous patches, but it is more probably due to the breaking down of superficial gummatous infiltration. This form of ulceration generally occurs on the septum, though the inferior turbinated body is occasionally affected. On examination the ulcer is found to be quite on the surface and rather depressed in the centre. It is covered with a thick, stringy mucus, and on wiping this away the ulcer itself is seen to be of a pinkish colour. It is not very painful or sensitive, but bleeds readily on probing. It shows no tendency to spread. The treatment consists in the administration of mercury and iodide of potassium internally, and locally a cleansing nasal wash should be used.

3. *Deep ulceration and necrosis.*—This is a fairly frequent result of syphilis. The periods of greatest danger are from one year to three years and from eight to fourteen years after infection, from three years to eight years being the period of greatest freedom. As deep ulceration is seldom seen without necrosis, the two conditions must be described together. Whether the gummatous deposit is originally in the submucosa or in the bone the result is the same in either case—viz., ulceration and necrosis. The septum is by far the commonest seat of the deposit, and, as before stated, the trouble is usually unilateral in the first instance. The process, however, tends towards the destruction of both cartilage and bone with such rapidity that perforation may occur and the opposite side may become involved at an early date. Just as a gumma of the nose is seldom seen in its typical form owing to the rapidity with which it breaks down, so in like manner the typical punched-out deep crateriform ulcer of tertiary syphilis is seldom seen, for masses of granulations spring up all round the ulcer with equal rapidity and again alter the appearance. This is the stage in which tertiary syphilis most frequently comes under observation, and on examination the septum is seen to be ulcerated, and around and bulging over the ulcer there is a mass of red granulations on probing, amongst which bare bone is easily reached. Similar processes may attack the turbinated bodies, and rarely may be confined to them, and the floor and the roof of the nose may also be involved. The discharge is at first purulent and blood-stained and contains shreds of necrotic tissue, but later it dries and forms large crusts which are extruded from the nostrils with great difficulty. These crusts undergo putrefaction and give rise to a most unpleasant odour, which is increased by their preventing the escape of necrosed bone. This smell is as bad as that arising from ozæna, though it differs from it in character. At first the patient is himself conscious of the smell and is greatly distressed thereby, but as the disease advances all sense of smell is abolished and the patient is unaware of the offensive odour of the nasal discharges. Sometimes the crusts are discharged by the patient, but more often they have to be removed by the surgeon, and in either case they tend to re-form. As a consequence of these processes the patient's general health is apt to suffer and he gets the appearance and symptoms of chronic septic poisoning. As the disease progresses the septum quickly becomes perforated and around the perforation red angry granulations spring up. These conditions may be hidden by the presence of black crusts, so that they may be overlooked unless looked for. Later still, especially in neglected cases, large fibrous polypi may develop, which are sometimes sessile and sometimes pedunculated. They may spring from either the septum or the turbinated bodies, and they develop *pari passu* with the destruction of the muco-periosteum covering these structures. They are devoid of epithelium, very red, and extremely hard and firm, and are consequently quite unlike ordinary polypi. The great characteristic, however, of tertiary syphilis in the nose is necrosis. It nearly always occurs in cases which are allowed to go on untreated and very often will occur even in spite of every form of treatment. Any or every structure within the nose may be partially or completely destroyed. As a rule the vomer is the first part to suffer, large portions of it separating and coming away. The cartilaginous septum and the nasal bones suffer next in order of frequency, then the floor of the nose, and lastly, the turbinated bodies, and with any of these the roof of the nose may be attacked. Necrosis of the floor naturally results in perforation of the hard palate, and necrosis of the roof may prove a most serious complication owing to secondary cerebral troubles.

4. *Scars, adhesions, and deformities.*—When healing is established the contents of the nasal fossæ may be altered almost beyond recognition. Adhesions, overgrowths, bridges, and abnormal cavities may all help to destroy the usual appearances of the interior of the nostrils. And as within the nostrils so without. The shape of the nostrils and the whole nose may be completely changed, the amount of distortion depending on the particular structures which have undergone destruction. On the other hand, it must be remembered that there may be great loss within without any sign of it exteriorly. For instance, nearly the whole vomer and even part of the cartilaginous septum as well may disappear without any alteration in the shape of the nose, and the same holds good when the turbinated or ethmoid bones are destroyed. Should, however, the vomer and the nasal bones both be destroyed marked deformity will result. This deformity is known as the "saddle-backed" nose. The upper part of the bridge as far as the nasal bones extend sinks into the face, leaving the anterior portion prominent and upturned. This is the commonest form of deformity in congenital syphilis, but it is not so often met with in the acquired disease. Another very common deformity is the depression of the anterior third of the nose. This is caused by the destruction of the whole of the cartilaginous septum and perhaps part of the bony septum. A third deformity is called the "bulldog" nose and is the result of the other two combined. The whole nose sinks bodily into the face, leaving just two upturned slits for nostrils. This deformity is the result of the destruction of the vomer, the cartilaginous septum, and the nasal bones all together. Lastly, the cartilaginous alæ may be destroyed, which may lead to various deformities from loss of substance, contractions, and adhesions, and even complete closure of one or both nostrils may occur. Such deformities are very commonly met with.

Complications.—Various complications may occur in the course of nasal syphilis, of which middle-ear troubles are, perhaps, the most important and most frequent. In the early stages the middle ear may be attacked with acute catarrhal otitis; during the necrotic stage purulent otitis is very common and is due to infection, and later still deafness from stenosis of the Eustachian tubes due to the formation of adhesions may occur. Again there are considerable risks of suppuration occurring in the accessory sinuses of the nose, the walls of which may be involved in the necrotic processes, so that when the disease has quieted down in the nose it may be necessary to treat the sinuses before complete relief can be obtained. Finally, pharyngitis and laryngitis sicca are of very common occurrence. Perforation of the hard palate and cerebral complications have already been mentioned.

Diagnosis.—The diagnosis of tertiary syphilis of the nose is fairly easy. In the earlier stages of the ulcerative process lupus and malignant disease are the troubles with which tertiary syphilis may be confounded and in the later stages when crusts have formed it may be mistaken for ozæna. The following are a few of the chief points which must be borne in mind in arriving at a diagnosis. In lupus the patient is generally younger than in acquired syphilis, the ulceration is very sluggish, and the ulcers are numerous, small, and superficial, and surrounded by fungus-like red or pale granulations. They are also more diffuse and occur as frequently on the turbinated bodies as on the septum. The overgrowth is in excess of the ulceration and there are often signs of lupus either on the face, on the exterior of the nose, or in the throat. The discharge is scanty; crusts, if they are present, are small and without any offensive odour; and there is but rarely any necrosis. Finally, lupus does not yield to iodide of potassium, and if any doubt remains a microscopic examination will greatly help the diagnosis. In malignant disease the patient is generally older, the growth is in excess of the ulceration, and the ulceration is on the surface of the growth. There are no crusts, bleeding is readily induced, and there is a history of frequent epistaxis. Pain is marked and the growth is very friable. Finally, here, again, iodide of potassium is of no avail, and a microscopic examination of a portion of the tumour will generally determine the

diagnosis. In ozæna (limiting the term to atrophic rhinitis) the odour is different and characteristic, there is no ulceration and no granulations or necrosis, and there is marked atrophy of the inferior turbinated bodies. After clearing away the crusts there is but little possibility of a mistake. It must be remembered, however, that it is possible to get true ozæna as a sequel to syphilis in cases in which there has been great destruction of the parts causing too great a patency of the nasal fossæ and in which the mucous membrane has undergone extensive alteration. The ozæna is the result of syphilis, but not part of the syphilitic process. In cases of perforation of the septum the question may arise as to whether it is due to syphilis or to rhinitis sicca. Generally speaking, if the perforation is large and involves the bony septum it is the result of syphilis, but if the perforation is small, more or less circular, and confined to the cartilaginous septum, it is generally due to rhinitis sicca, signs of which are usually seen in the nose. Small perforations may also be occasionally due to trauma.

Treatment.—The general treatment must be on the lines already suggested. Locally the nasal passages must be cleansed and cleared as soon as possible of all crusts and necrotic tissue, sequestra must be removed with forceps, and the granulations must be scraped away with a curette, and the patient must afterwards keep the passages clean with an alkaline lotion. In obstinate cases after cleansing, heated calomel should be insufflated and the nose should be packed with double cyanide gauze. The gauze should be changed daily, about which there is no difficulty as the patient can easily be taught to do it for himself. Packing the nose has a marked effect in preventing the formation of crusts and in keeping the mucous membrane clean and moist.

SYPHILIS OF THE NASO-PHARYNX.

Primary and secondary syphilis of the naso-pharynx are very rare. The primary sore has been observed in this region, and is generally the result of careless instrumentation, especially with the Eustachian catheter. During the secondary period ulcerating papules and mucous patches may occur. They are usually discovered in patients seeking advice for the acute or sub-acute middle-ear catarrh which so often accompanies secondary syphilis.

Tertiary syphilis in this region is by no means rare, and though there are generally signs of the disease in the nose or pharynx as well, yet occasionally the naso-pharynx is the first place to be involved by tertiary syphilis, and may sometimes be alone affected. In such cases the symptoms are pain and aching at the back of the throat, deafness, tinnitus, and headaches, the presence of a discharge which is often blood-stained, and difficulty of breathing per nares. On examination there is seen either on the vault of the naso-pharynx or on the posterior surface of the velum a swelling with a sharply cut, deep ulcer in its centre. The shape of the ulcer varies and the size is anything from that of a threepenny-piece to that of a shilling. When the velum is attacked its whole substance is thickened, its anterior surface is much inflamed, and it is liable to become very quickly perforated.
